
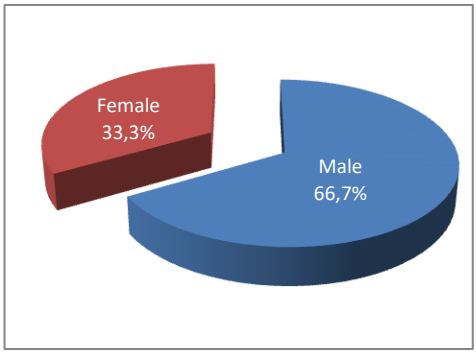

Fig. 1. Gender distribution among patients with myocardial bridges

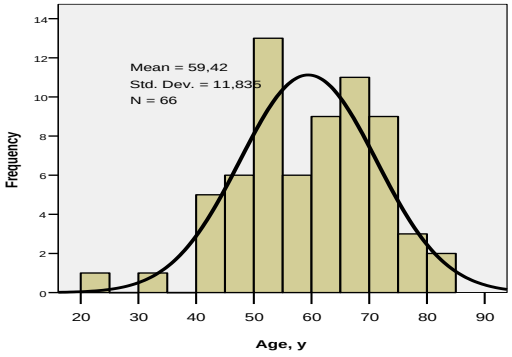

Fig. 2. Diagnostic age histogram for patients with myocardial bridges

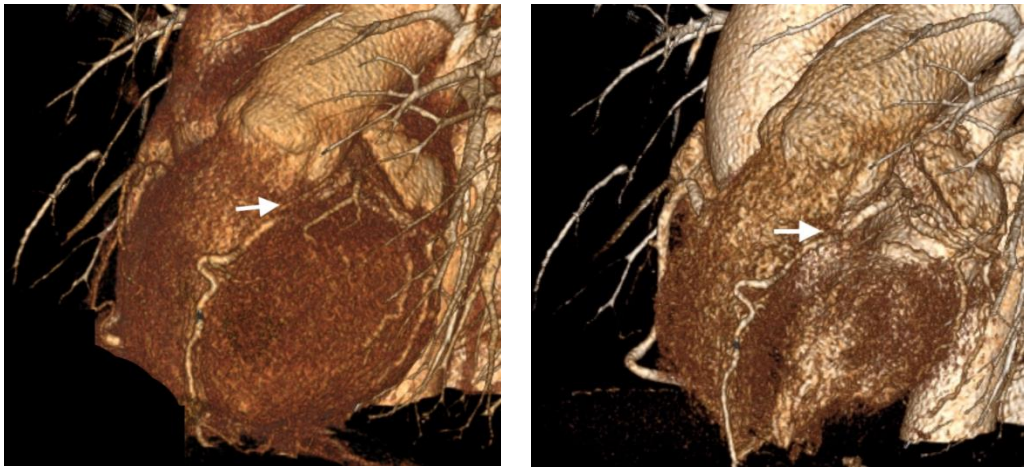

Fig. 3. 3-dimensional volume-rendered images obtained from coronary computed tomography angiography of a myocardial bridge in the middle segment of the left anterior descending artery in a female patient

In 97% of cases, the primary coronary artery affected was the left anterior descending artery (LAD) (fig. 3). Only one instance of myocardial bridge was observed

on the right coronary artery (RCA) and another one on the left main (LM).

The middle segment of the LAD was the most common site of myocardial bridges localization, accounting for 62.5% of total bridges found (tab. I).

TABLE I.

Localization of myocardial on the left anterior descending artery (LAD), left main (LM) and right coronary artery (RCA)

Characteristics	Coronary		
	LAD (n=64)	LM (n=1)	RCA (n=1)
Location			
proximal	11 (17.2%)	1 (100%)	1 (100%)
medial	40 (62.5%)	0 (0%)	0 (0%)
distal	12 (18.8%)	1 (100%)	0 (0%)

Furthermore, our investigation explored the primary characteristics of myocardial bridges, examining their morphology concerning length and width, as well as the presence of stenosis (tab. II). Analysis of myocardial bridge depth revealed that the majority of patients (69.7%) exhibited deep myocardial bridges, with a smaller proportion presenting very deep myocardial bridges (16.7%), and a further subset displaying superficial myocardial bridges (13.6%) (tab. II). In terms of length, data indicated that a significant portion of patients (74.2%) had short myocardial bridges, while the remaining 25.8% presented long ones.

TABLE II.

Characteristics of myocardial bridges

Myocardial bridges Coronary Artery	N	%
LAD	64	97.0
LM	1	1.5
RCA	1	1.5
Location on the coronary artery		
Proximal	13	19.7
Medial	40	60.6
Distal	13	19.7
Width (mm)		
Mean ± SD	3.02±1.22	
median/limits	2.50/1.3-6.0	
Thickness (mm)		
< 2	9	13.6
2-5	46	69.7
≥ 5	11	16.7
Length (mm)		
Mean ± SD	20.33±9.25	
median/limits	18/8-50	
Dimensions		
Short	49	74.2
Long	17	25.8

The mean width measured 3.02 ± 1.22 mm, indicating a relatively consistent range. Conversely, the mean length was 20.33 ± 9.25 mm, demonstrating a wider dispersion of values. Simultaneously, 24 patients exhibited stenosis on the LAD, with only one case showing involvement of the RCA (tab. 3). When evaluating the degree of the stenosis of the affected coronary arteries, the results revealed a mean value of 13.26±21.13. There were 12 patients (18%) who presented stenosis ≥50%, and just one patient with stenosis >70%. Nevertheless, in our study, only 3 male patients (5%) underwent stent placement.

TABLE III.

Morphological aspects of myocardial bridges

Characteristics	Coronary		
	LAD (n=64)	LM (n=1)	RCA (n=1)
Stenosis	24 (37.5%)	0 (0%)	1 (100%)
Thickness			
< 2 mm	9 (14.1%)	0 (0%)	0 (0%)
2-5 mm	44 (68.8%)	1 (100%)	1 (100%)
≥ 5 mm	11 (17.2%)	0 (0%)	0 (0%)
Length			
Long	17 (26.6%)	0 (0%)	0 (0%)
Short	47 (73.4%)	1 (100%)	1 (100%)

Our analysis of the coronary artery calcium score revealed a heterogeneous distribution among patients. While a substantial portion (42.4%) exhibited a mild score, a significant proportion (40.9%) presented zero scores, indicating absence of calcification. Additionally, a smaller percentage (9.1%) exhibited severe scores, while moderate scores were observed in just 7.6% of cases (fig.4). This spectrum of findings underscores the differences of calcium deposition within the coronary arteries with myocardial bridges, suggesting varying degrees of cardiovascular risk among the studied population.

Our observations revealed a significant elevation in the average calcium score level among males (p=0.025) (fig.5).

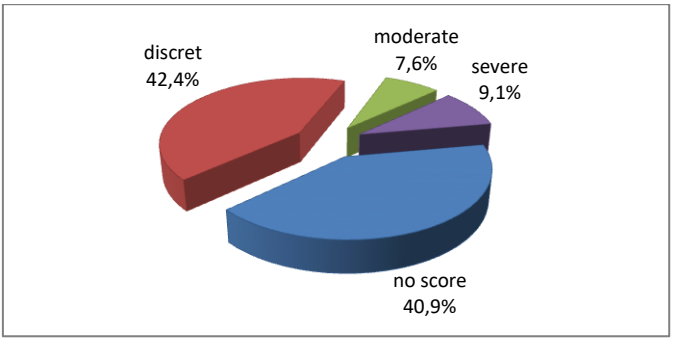

Fig. 4. Coronary Artery Calcium Score in patients with myocardial bridges

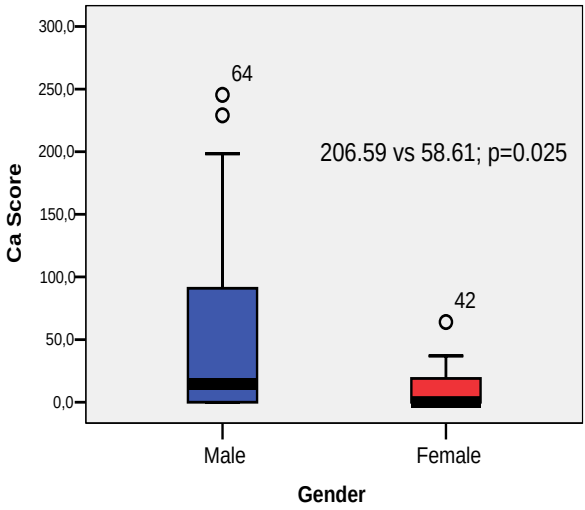

Fig. 5. Average calcium score levels by gender

Simultaneously, the average calcium score level was significantly higher in individuals with a myocardial bridges thickness exceeding 5 mm (p=0.025) (fig. 6).

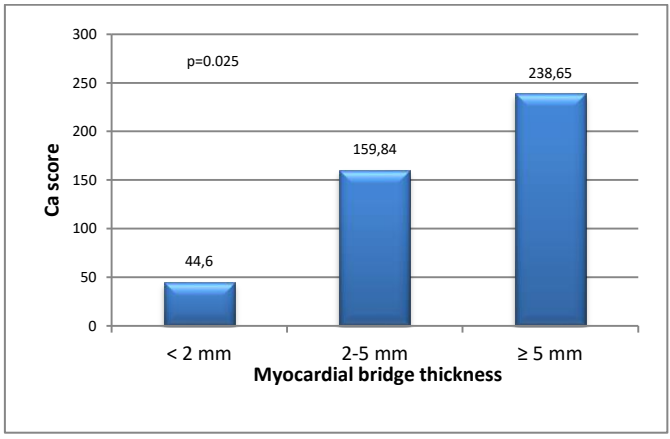

Fig. 6. Comparison of Average Calcium Score Levels between Myocardial Bridge Thickness Groups

Our investigation into the prevalence of hypertension, dyslipidemia, coronary artery disease (CAD), and chronic heart failure among these patients offered promising insights, observing a predominant occurrence of these conditions in males. Hypertension manifested in 29 patients (44%), with a noteworthy observation that half of the male cohort was affected by this condition. Dyslipidemia was observed in 9 male individuals and 6 female patients. Furthermore, CAD was identified in 25 patients (38%), while chronic heart failure was diagnosed in 17 individuals (26%) (tab. IV).

TABLE IV.
Associated conditions by gender in patients with myocardial bridges

Comorbidities	Male (n=44)		Female (n=22)		Chi² Test p	RR	IC95%
	n	%	n	%			
Hypertension	22	50.0	7	31.8	0.157	1.68	0.79-3.57
Dyslipidemia	9	20.5	6	27.3	0.537	1.14	0.73-1.80
Coronary artery disease	18	40.9	7	31.8	0.470	1.31	0.62-2.76
Chronic cardiac failure	14	31.8	3	13.6	0.098	2.20	0.74-6.51

DISCUSSION

The large spectrum of coronary artery anomalies comprises of a variety of rare congenital conditions, exhibiting diverse morphologies, clinical presentations, and potential hemodynamic implications (8).

Myocardial bridges, included within this category, are distinguished by a segment of the coronary artery taking an intramuscular route, diverging from its usual superficial path over the myocardial tissue and, instead, traversing through the myocardium itself. Therefore, this anomaly may impact not only the anatomy of the coronary arteries, but also the blood flow distribution among the myocardium(9).The extent of this effect fluctuates depending on the degree of compression in the bridged region during contraction, creating a 'milking' action that reduces blood flow and could predispose to ischemia. This dynamic presentation not only influences myocardial perfusion, but also shapes the occurrence and diversity of clinical manifestations in patients with myocardial bridges, resulting in highly variable expressions among individuals (10).

Their identification is now achievable through both invasive methods, such as Intravascular Ultrasound (IVUS) or coronary angiography, and non-invasive approaches like echocardiography, CCTA and Cardiac Magnetic Resonance Imaging (CMRI) (5). Echocardiography serves as a valuable tool for detecting myocardial bridges, although its specificity is limited-it may reveal irregularities in the septal wall motion from end-systole to early-diastole, alongside preserved heart function in the apex(4).Non-invasive imaging techniques, particularly CCTA, offer the highest accuracy and specificity in detecting myocardial bridges. CCTA alone can detect up to 86% of cases, emphasizing its efficacy. In contrast, the prevalence of myocardial bridges detected via coronary angiography is a mere 1.7%. This discrepancy underscores the superiority of non-invasive methods in identifying these anomalies (5). At the same time, CMRI, due to the lack of contrast administration or radiation exposure, is preferable for younger athletes and patients with kidney failure. Recent studies show its superiority over MDCT in detecting calcified coronary artery lesions, but its use in detecting myocardial bridges is still limited due to the poor spatial resolution (11, 12). Our study revealed a detection rate of myocardial bridges at 0.51% among all patients scanned (12758). Remarkably, among all coronary artery anomalies observed, myocardial bridges ranked as the third most common, accounting for up to 18.9% of cases (13).

In our study, we included patients aged 22 to 84 years, with a mean age of 59.42 years ± 11.84, reflecting the diverse age range at which myocardial bridges are

identified. Furthermore, we noted a predominant presence of male patients with myocardial bridges (66.7%), consistent with findings from prior studies, thereby underscoring their heightened prevalence among men (2).

While myocardial bridges may occur across any of the primary coronary arteries, prevailing research underscores their most common occurrence along the left anterior descending artery (LAD), especially within its middle segment (10). Our study corroborates this notion, particularly evident in the predominant presence of myocardial bridges in the LAD in 97% of cases. Additionally, a small minority of cases (3%) featured myocardial bridges on the right coronary artery (RCA) and left main coronary artery (LM). However, our findings reveal a distribution pattern within the myocardial bridges localization: the middle portion was most frequently affected, observed in 40 patients, followed by the distal and proximal segments, each exhibiting nearly comparable prevalence rates (18.8% and 17.2%, respectively).

Debates persist over the role of myocardial bridges within the structure of the coronary artery, with discussions focusing on their potential protective or detrimental impacts. Coronary atherosclerosis involves the formation of plaques into the main arteries of the heart, predisposing to the development of thrombotic events triggered by their rupture (14). Though some theories propose that myocardial bridges may offer protection against atherosclerosis development, additional research is necessary to validate this hypothesis. Several studies revealed that the vascular segments with myocardial bridges exhibit a notable reduction in the occurrence of atherosclerotic lesions compared to those without it (6).

In our study, 38% of the patients exhibited stenosis on the coronary artery affected by the myocardial bridge, with a majority of 24 cases involving the LAD. Simultaneously, we examined the calcium score, also referred to as the Agatston Calcium Score, to assess the presence and extent of calcium buildup within the coronary arteries while utilizing CCTA. This score serves as a predictive instrument for imminent cardiovascular disease progression and helps in shaping therapeutic strategies. At the same time, it is an important non-invasive tool that could not only be used in evaluating the patients with clinical manifestations, but also in asymptomatic individuals with low to moderate risk of developing CAD (14). The observation that 41% of patients in our study recorded a zero-calcium score, indicating a reduced likelihood of developing CAD in the near term, alongside 42% displaying mild scores, could further highlight the potentially protective function of myocardial bridges in the coronary arteries. At the same time, only a small percentage of patients (18%) presented stenosis ≥50%. Despite only 17% of patients exhibiting moderate and severe calcium scores, careful consideration is warranted. Concurrently, our study revealed a noteworthy increase in the average calcium score level among males ($p=0.025$). These findings underscore the necessity for ongoing surveillance of the patients, given the unpredictability of myocardial bridge manifestations and clinical outcomes.

Two primary characteristics of myocardial bridges are their length, spanning between four and forty millimeters, and their depth, ranging from one to ten millimeters (15).A meta-analysis study indicated that, through angiography and CCTA, the average length of myocardial bridges was 21

millimeters, with a depth of 3 millimeters. Autopsy findings revealed a mean length of 19.3 millimeters and a depth of 3.2 millimeters for myocardial bridges. Nevertheless, it is evident that even subtle variations may arise, influenced by the method of investigation-whether invasive (angiography) or non-invasive (CCTA), as well as through autopsy (1). Despite these differences, the dimensions remain remarkably similar across the various modalities. In our study implying the evaluation of myocardial bridges through CCTA the mean length was 20.33±9.25, while the width was 3.02±1.22.

Based on their depth, we classified myocardial bridges as superficial (1-2mm), deep (≥2 and <5mm), and very deep (≥5 mm). The majority of myocardial bridges were deep, with 44 individuals presenting it on the LAD and two patients on the RCA, respectively on the LM. Superficial and very deep myocardial bridges were present in almost the same proportions, with just two more patients presenting superficial compared to very deep. Simultaneously, regarding their length, myocardial bridges were categorized as short (<25mm) and long (≥25 mm), with only 25.8% presenting long myocardial bridges. Clinical significance in myocardial bridges is typically defined by a depth of≥2 mm and a length of≥25 mm (4). In our study, we found that 26% of the patients met this criterion, with 6 individuals exhibiting long and deep myocardial bridges (9%) and 11 individuals displaying long and very deep myocardial bridges (17%). At the same time, a higher value of the depth is associated with increased chance for the development of cardiovascular events (4). This theory is further supported by one of our findings, which indicated a higher average calcium score level in individuals with a myocardial bridge thickness exceeding 5 mm (p=0.025). This suggests an elevated risk of potential rupture of atherosclerotic plaques, thereby predisposing individuals to acute coronary syndromes.

Typically, most myocardial bridges are benign and asymptomatic, particularly when their depth is less than one millimeter. However, they can occasionally become clinically significant. Their initial presentation may manifest as angina (stable, unstable or vasospastic), often occurring during systole when the myocardial bridge is compressed (5, 11).Unstable angina was more frequently identified in patients affected by this anomaly than troponin-positive myocardial infarction (5). Nevertheless, there are no correlation between the severity of the angina and the dimensions of the myocardial bridge (1).More severe manifestations include Takotsubo syndrome, heart blocks, or, in extremely rare cases, sudden death (5). Research indicates that male patients affected by this anomaly are at elevated risk of experiencing ventricular tachycardia or premature ventricular contractions during physical exertion. This heightened risk is attributed to the occlusion of the coronary artery, potentially leading even to sudden death, scenario also observed in high-performance athletes with myocardial bridges (1, 16).

Currently, there are several hypotheses regarding the development of myocardial ischemia in these patients. In healthy individuals, 80% of coronary flow occurs during diastole, but in those with myocardial bridges, systolic compression disrupts this normal flow pattern. Concurrent tachycardia can further reduce diastole, exacerbating myocardial bridge manifestations and

increasing oxygen consumption, potentially leading to ischemia. Another phenomenon is the “branch steal" in myocardial bridges, resulting in lower diastolic pressures in the affected segment and more local ischemia in mild-moderate bridges compared to distal myocardium. Additionally, the continuous milking effect of the anomaly exposes sub-endothelial tissue and activates the coagulation system, thereby increasing the risk of intracoronary thrombogenesis and raising questions about the true extent of their contribution to cardiovascular mortality (11, 16).

In our research, we explored the presence of hypertension as a potential accelerator of atherosclerosis and, consequently, CAD. Our findings revealed that hypertension was prevalent in 44% of the patients, notably affecting 50% of male participants. Similarly, when investigating the presence of CAD, we observed its occurrence in 38% of the patients, predominantly affecting 18 male patients compared to only 7 female patients. Additionally, fewer patients exhibited chronic cardiac failure, with a majority of affected individuals being male. These observations underscore a gender disparity in the prevalence of cardiovascular conditions among individuals with myocardial bridges, with men exhibiting a higher frequency of hypertension, CAD, and chronic cardiac failure compared to women. Nevertheless, in our study, dyslipidemia was present only in 15 patients (23%).

In such clinical scenarios, pharmacological treatment is necessary to alleviate symptoms arising from concurrent disorders such as arrhythmias, hypertension, or hypertrophy (5). In the therapeutic management of myocardial bridges, beta-blockers are prioritized to optimize hemodynamic function, followed by non-dihydropyridine calcium channel blockers, which have a vasodilator effect and are able to improve symptomatology. Additionally, antiplatelet therapy should be considered to prevent and mitigate acute events in hypertensive patients with coronary artery disease (CAD) (5, 1).

In cases where pharmacological interventions prove inefficient and the affected coronary artery exhibits significant stenosis, stent implantation may emerge as the preferred solution. Prior studies have demonstrated enhanced clinical outcomes following coronary stenting in patients with myocardial bridges. However, in situations where neither medical treatment nor coronary stenting are feasible, surgical myotomy may be considered. Alternatively, another surgical option entails the anastomosis of the internal mammary artery (IMA) to the LAD (2). Finally, coronary artery bypass grafting may be considered in severe cases of myocardial bridges with significant hemodynamic impact and dimensions exceeding 25 millimeters (1). In our study we observed that only three male patients needed coronary angioplasty with stents, comprising just 5% of the total patient population, suggesting that only in certain situations myocardial bridges may lead to severe enough hemodynamic compromise to necessitate invasive interventions.

CONCLUSIONS

Utilizing a sensitive and precise investigative technique such as CCTA improves the detection of clinically significant myocardial bridges, with the middle segment of the left anterior descending artery being the primary site in most cases. The study suggests a potential link between myocardial bridges thickness and higher coronary artery

calcium scores, prompting further exploration. Correlations with atherosclerosis and hypertension require deeper investigation for a comprehensive understanding of myocardial bridges clinical impact.

CONFLICT OF INTEREST AND FUNDING

The authors declare no conflicts of interest. This research received no external funding.

URINARY NEUTROPHIL GELATINASE-ASSOCIATED LIPOCALIN IN CHILDREN WITH RECURRENT URINARY TRACT INFECTIONS IN NORTH-EASTERN ROMANIA (Abstract): Urinary Neutrophil Gelatinase-Associated Lipocalin (uNGAL) is currently proposed as an improved diagnostic tool for urinary tract infection (UTI). Both normal and pathological standardized values are lacking. There is some evidence that children with recurrent UTI may have lower uNGAL values, thus promoting it as a prognostic biomarker. **Aim**: To compare baseline uNGAL values in patients with recurrent UTI to controls without history of UTI. **Materials and methods**: Patients and/or their caretakers signed an informed consent prior to participation. Recurrent UTI (rUTI) was defined as history of at least 2 UTI episodes in the last 6 months or 3 in the last year, confirmed by positive urine culture. The correspondent control group had no history of UTI. Obtained urine samples were frozen and kept until uNGAL assay measurement was performed as per the manufacturer's recommendations. Data analysis was performed using IBM® SPSS Statistics (version 29.0.20 (20)). **Results**: We found a significant difference in uNGAL values between the rUTI group and the control group (p=0.01), AUC = 0.815, cutoff = 5.27 ng/mL (TPR =1, FPR =0.3). uNGAL values in the rUTI group were not correlated with age (Pearson r = 0.243, p =0.423). uNGAL values were higher in the rUTI group. **Conclusions**: Patients with history rUTI have higher uNGAL values than those without history of UTI. uNGAL does not seem to be a protective factor and low values do not seem to be a predictive diagnostic tool for pediatric UTI. Further studies should take into consideration the patient's history of UTI regarding cut-off values. **Keywords**: NGAL, PEDIATRIC, RECURRENT URINARY TRACT INFECTION.

Urinary tract infection (UTI) in infants and young children is an important bacterial infection that can lead to permanent renal function loss. Current diagnosis options have low sensitivity and specificity and definitive diagnosis may postpone antibiotic administration up to 48 hours. Neutrophil gelatinase-associated lipocalin is a relatively new renal biomarker that has shown promise in early diagnosis of UTI and potential renal scarring. Baseline values of uNGAL have been proposed (1, 2), but a recent meta-analysis (2) has shown that underlying patient characteristics may influence determining cut-off values. Our study aims to compare the values of uN-

GAL in a population with history of rUTI, with a control group of patients without history of UTI from pediatric patients in Northeastern Romania, in order to check if baseline uNGAL values remain the same after having suffered UTI and to test if uNGAL can be considered a prognostic factor for UTI.

MATERIALS AND METHODS

This study was approved by the "Sf. Maria" Emergency Clinical Hospital for Children Ethics Committee (no. 5075/17 February 2021) and the "Grigore T. Popa" University of Medicine and Pharmacy Iași's Ethics Committee (no. 8753/28 May 2020) and informed consent was obtained prior to participation. Cases were patients with ages between 3 months and 18 years with a history of recurrent UTI (rUTI), from the Department of Pediatric Nephrology at "Sf. Maria" Emergency Clinical Hospital for Children from March 2021 to March 2022. RUTI was defined by two or more culture proven UTIs with at least 100,000 CFU/mL of a single urinary pathogen in the last 6 months, respectively three or more in the last year. Control patients were a convenience sample enrolled from the General Pediatrics Department at "Sf. Maria" Emergency Clinical Hospital for Children. Patients who provided urine samples for routine clinical purposes were approached for inclusion in this study as controls. None of the control patients required fluid replacement, resuscitation or hospital admission, or had any clinical parameters to suggest dehydration, such as tachycardia or decreased urine output. Controls were excluded if they had a history of a UTI, evidence of a UTI at the time of enrollment (proven UTIs with at least 100,000 CFU/mL of a single urinary pathogen), known or suspected renal dysfunction, or had any urologic history.

The following parameters were studied: patient diagnosis at the moment of admission, number of UTI recurrences, urinalysis and presence of pyuria, urine culture, presence of malformation, age and sex of the patient and presence of antibiotic prophylaxis in relation to the values of urinary NGAL.

A minimum of 5 mL of urine were collected from cases and controls. Samples were centrifuged, aliquot and stored at -80 degrees Celsius within 12 hours of collection. UNGAL measurements were performed as per manufacturer's recommendations in triplicate using *Human Neutrophil Gelatinase-Associated Lipocalin / NGAL (LCN2) ELISA Kit* from producer Abbexa®. Patient data was collected from the electronic medical record. Data was introduced in IBM® SPSS Statistics (version 29.0.20 (20)). Grouping variable statistics was analyzed. Non-parametric distributed variables, i.e. uNGAL in the risk and healthy patients were compared using the Mann-Whitney-U test. The area under the receiver operator characteristic (ROC) curve for identifying rUTI involvement was calculated using logistic regression models for uNGAL. The optimal uNGAL cut-off point for the identifying rUTI involvement, as well as the associated sensitivity and specificity were calculated. A p value of < 0.05 was considered statistically significant. The datasets generated during the current study are available from the corresponding author on reasonable request.

RESULTS

A total of 13 patients (10 female, 3 male) aged between 3 months and 18 years with recurrent UTI were introduced in the study, with 10 case controls with appropriate age/sex distribution.

Of the 13 patients, 2 had no demonstrated underlying malformation, while 11 presented different types of congenital anomalies of the kidney and urinary tract CAKUT (6 presented with different degrees of VUR (1-5) including one secondary to posterior urethral valve, 2 presented right kidney hypoplasia, 2 presented kidney hypoplasia, 1 neurogenic bladders). 7 of the 13 patients had received antibiotics as prophylaxis for UTI prior to admission.

All patients had history of at least 2 infections previous to the current admission. Of these 5 had a recurrence of 2 infections, 1 presented at least 3 infections, 2 had 4 recurrences and 2 had at least 6 infections by the time of admission. 3 of these patients had presented with more than 6 infections.

Pyuria (defined as above 10 leucocytes/ high-power field) was not found in any patients. Urine culture was negative (<1000 CFU/mL) in all patients. Creatinine values varied from 0.35 to 0.86 mg/dL. Creatinine clearance varied from 82.67 to 172.85 mL/min/1.73m^2 with a median of 111.27 mg/dL.

Of the 13 patients with rUTI, only 5 had undergone DMSA scan to confirm scarring. 3 of 5 presented 1 kidney scar, the rest presented 3 or more kidney scars.

uNGAL values varied from 5.78 ng/mL to 31.93 ng/mL in the rUTI cases, with a mean value of 16.23 ng/mL and a median of 13.74 ng/mL. The control group uNGAL values were between 0.17 ng/mL and 19.38 ng/mL, with a mean of 6.49 ng/mL and median of 3.39 ng/mL. Further description of uNGAL (ng/mL) value distribution can be seen in first table.

TABLE I.

uNGAL (ng/mL) distribution descriptive values

		uNGAL_rITU	uNGAL_control
Number of patients	Statistic	13	10
Range	Statistic	26.15	19.21
Minimum	Statistic	5.78	.17
Maximum	Statistic	31.93	19.38
Mean	Statistic	16.2377	6.4920
	Std. Error	2.62642	2.15737
Std. Deviation	Statistic	9.46970	6.82220
Variance	Statistic	89.675	46.542
Skewness	Statistic	.857	1.053
	Std. Error	.616	.687
Kurtosis	Statistic	-.689	-.454
	Std. Error	1.191	1.334

Mann-Whitney U and Wilcoxon W test were applied to test whether rUTI and control groups have identical (H0) or different uNGAL distributions (H1). uNGAL values were significantly higher in the rUTI group than in the case control (p =0.011) (Asymp. Sig. (2-tailed) = 0.011) (tab. II). uNGAL value distribution in the rUTI risk group and case control group are listed in first figure.

TABLE II.
Statistical test

	uNGAL
Mann-Whitney U	24.000
Wilcoxon W	79.000
Z	-2.544
Asymp. Sig. (2-tailed)	.011
Exact Sig. (2*(1-tailed Sig.)) (not corrected for ties)	.010

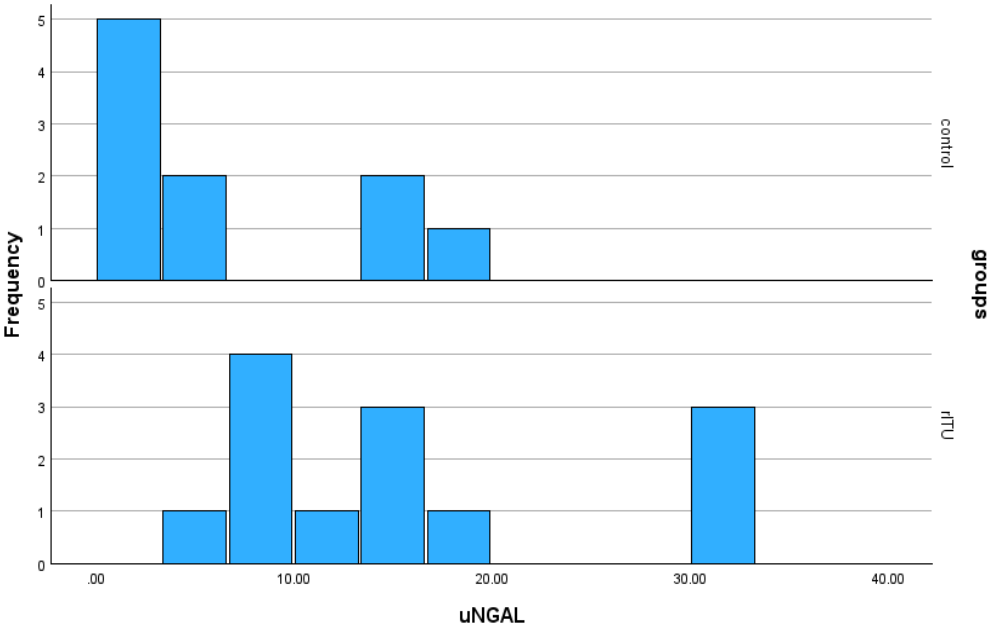

Fig. 1. uNGAL (ng/mL) value distribution in the rUTI risk group and case control group

ROC-AUC curve for NGAL values suggested the best cutoff points of 5.27 ng/mL FPR = 0.3, TPR = 1 with AUC = 0.815 (fig. 2).

Seven patients had various degrees of VUR (grade 1-5). For these patients, no significant correlation was found between uNGAL values and VUR degree (Pearson Correlation -0.173, p=0.711).

No significant correlation was found between uNGAL values and age expressed in months (Pearson Correlation 0.243, p=0.423), height expressed in cm (Pearson Correlation 0.098, p=0.750) or weight expressed in kg (Pearson Correlation 0.202, p=0.508).

uNGAL values did not significantly correlate with creatinine (Pearson Correlation 0.088, p=0.775) or creatinine clearance (Pearson Correlation -0.171, p=0.577). Creatinine clearance was calculated by the Schwartz formula ((k*height(cm))/serum creatinine (mg/dL).

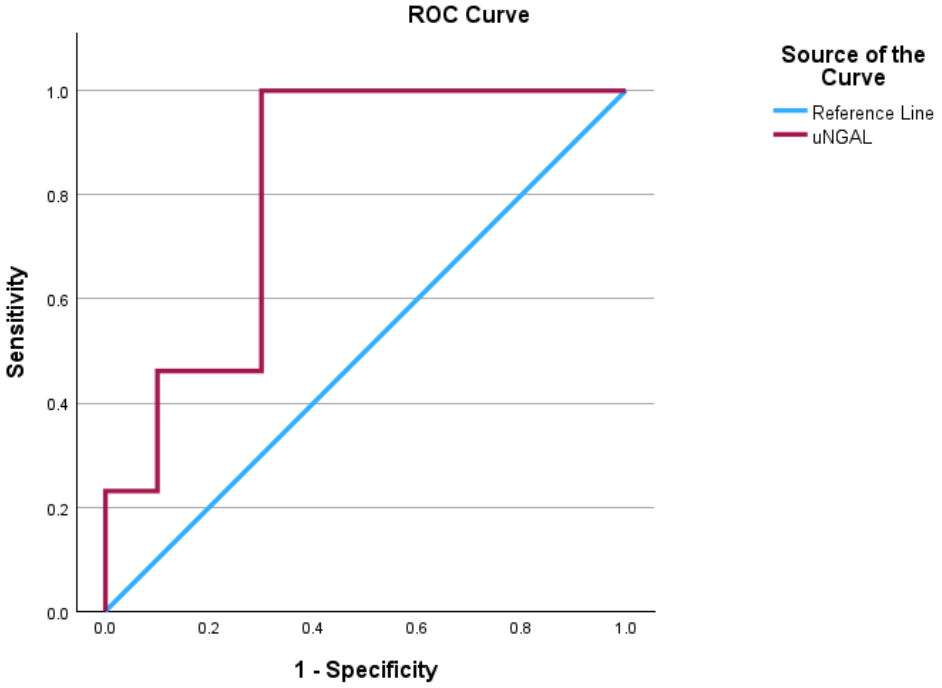

Fig. 2. ROC curve for uNGAL. AUC 0.815. p=0.002, (95% CI 0.62-1.01), cutoff uNGAL = 5.27 ng/mL, TPR = 1, FPR = 0.3.

DISCUSSION

Urinary tract infection (UTI) in infants and young children is an important bacterial infection with an incidence of 2% during the first 2 years of life. The prevalence of UTI is higher (5-24.2%) among children aged < 2 years presenting with fever (1-3). Early detection and proper management of UTIs is important since UTIs involving the kidney may cause permanent renal scarring and be a risk factor for future development of renal insufficiency (4). Other later-life risks related to renal scarring include hypertension, preeclampsia during pregnancy and proteinuria (5). Recurrent UTIs (rUTI) occur in approximately 12% of patients following an initial UTI (6). Acute pyelonephritis, especially in recurrent episodes may lead to renal parenchymal involvement and scarring with high prevalence rate (15%-60%) among children (7). Furthermore, it has been reported that while the incidence of primary VUR is 1% in the normal population it reaches 30–50 % in recurrent UTI and that 15–60 % of these affected children may have permanent renal scarring after the UTI (8).

Urinalysis is a convenient and readily available diagnostic option. However positive leucocyte esterase (LE) or nitrites have variable and often suboptimal sensitivities (78–88%) and specificities (72–97%) across different studies (9-11). These results are influenced by the different methods of urine collection and laboratory pro-

cedures (12). Inaccuracy of the UA leaves the physician to balance excess antibiotic treatment with potential toxicity and increase of antibiotic resistance risk against lack of action and potential kidney scarring. Therefore, it is difficult to provide a quick diagnostic of UTI in children and thus a reliable marker for the early diagnosis is warranted.

Tc-99m dimercaptosuccinic acid (DMSA) renal scintigraphy is considered the current gold standard in imaging renal parenchymal involvement during acute pyelonephritis (APN) and to detect late renal damage consequent to UTIs (13). Although DMSA scan is highly sensitive method in detecting renal inflammation and scaring, it is invasive to expose young children to radiation. Moreover, to confirm the diagnosis of renal scarring, DMSA must be repeated 4 to 6 months after the APN (13). Since consequences of renal scarring are serious, this aggressive method used to diagnose APN is justified. However, the need for a less invasive diagnostic tool is evident.

Numerous studies have evaluated the usefulness of inflammatory markers for predicting APN, and demonstrated that commonly used laboratory parameters such as white blood count (WBC), C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) have low sensitivity and specificity for accurately predicting acute renal parenchymal involvement. At present, these tests are not recommended for routine use to differentiate APN from lower UTI in children (14) .

New biomarkers have emerged with promising roles in early diagnosis and prognosis of UTI. Neutrophil gelatinase-associated lipocalin (NGAL), a member of the lipocalin family, is an excellent biomarker for predicting and monitoring acute kidney injury (AKI) of diverse etiologies. It is a promising marker for detection of subclinical renal damage due to vesicoureteral reflux (VUR), renal scarring, and obstructive uropathy (15).

NGAL is a member of the lipocalin family that plays an important role in the innate immune response to the bacterial infection. NGAL a protein expressed in neutrophils and other tissues, including the collecting duct of the kidney and released from activated neutrophils, to prevent bacterial iron uptake and growth. It has been linked with acute kidney injury, but urinary NGAL (uNGAL) is significantly elevated with gram-negative UTIs in both adults and pediatric studies (12, 16-18). Different studies found urine NGAL values were increased in both, upper and lower UTI. Urinary NGAL concentrations cut-off values have not yet been established. However, there is indication that uNGAL may decline with age in infants (19). Multiple studies have had controversial results. No current recommendations are made regarding the use of urinary NGAL in pediatric populations (20-25).

To the best of our knowledge, this is the first analysis of uNGAL in pediatric patients with recurrent UTI in northeastern Romania.

Both urinary and blood NGAL (plasma or serum) have been researched for early prediction of UTI and APN in children. A strong argument in favor of measuring uNGAL over pNGAL or sNGAL is the non-invasiveness of the procedure. A meta-analysis by Forster and Devarajan 2017 suggests using pNGAL for pyelonephritis

and renal lesion diagnosis, while uNGAL seems to be superior in diagnosing genitourinary lesions, subclinical scarring and obstructions (26).

In 2009 Ichino *et al*, in an experimental rat UTI model, observed a marked increase of urine NGAL (uNGAL) at the early stage of infection and thereby suggested a potential utility of uNGAL as a marker of APN in humans (27). Several clinical studies have been conducted to assess the diagnostic value of uNGAL for detecting APN, but the results are not clear and, in some cases, pNGAL appears to have higher utility (20-25, 28).

Our cutoff points are close to Kim BH *et al* 2014. They suggested that for a cutoff value of 5.75 ng/mL uNGAL had no significant correlation with UTI (29). While we found that uNGAL is significantly higher in the risk group, there is no statistical correlation between NGAL values in these patients and the presence of UTI at the moment of sample collection. This indicates that uNGAL may be elevated in patients with malformations, but not necessarily related to infection. There are important differences between the two studies, regarding the number of patients and the inclusion criteria.

We also note that values of uNGAL in patients with recurrent UTIs was not significantly smaller than healthy controls, as suggested by Forster *et al* 2017 (30). The result difference could be attributed to the small sample size in both study groups. Median uNGAL values in healthy controls in the Forster group was also higher than both our groups (27.61 vs 13.74 and respectively 3.39 ng/mL). This would indicate that uNGAL does not seem to be a protective factor or predictive diagnostic tool for pediatric UTI.

In comparison with the study of Yilmaz *et al*, 2009, (31) who noted a cutoff value of 20ng/mL for diagnosis of UTI, we would like to note that the median value of non-infected, rITU group patients is smaller than their control group. This may be why in that study the authors noted that higher values would increase the chance of UTI four times. The source of confounding factors could also be related to the age difference (2 months to 12 years compared to 3 months to 17 years), inclusion criteria and sample size.

Yim HE *et al*, 2014 noted that for UTI diagnosis in patients with fever the best cutoff value for uNGAL was 23.95 ng/mL. However, that study only included patients at their first symptomatic febrile UTI. In our study, 3 patients, including one without malformation that had recurrent UTI, presented uNGAL values above 24 ng/mL with a negative urine culture. This suggests that the utility of uNGAL is highly variable and that further research is required to establish the specific situations and related best cutoff-points (32).

There were some limitations of our study. We only evaluated urinary NGAL concentration, but not serum/plasma NGAL concentration. This was a single-center study, with a small cohort of children. In the present study, due to lack of constant test availability, we could not perform DMSA scan for all patients to confirm or differentiate APN from lower UTI. Age can also be considered a limiting factor, in regards to acceptance of introduction into the study. However, in the study we found no correlation between age and uNGAL levels. Patients with early stages of chronic kidney disease have been

shown to present increased levels of uNGAL. No correlation was found between creatinine clearance and uNGAL values in our study, and we have to take into consideration clearance modifications were marginal (lowest value was 82.67 mL / min / 1.73 m^2, and corresponding to a serum creatinine value of 0.43 mg/dL). Finally, reliable reference intervals for uNGAL are lacking for both healthy children and UTI patients.

CONCLUSIONS

Urinary NGAL is significantly higher in patients with a history of recurrent UTI (rUTI), than controls with no history of UTI, with the best cutoff point of 5.27 ng/mL (FPR = 0.3, TPR = 1) with AUC = 0.815.

Further studies that propose uNGAL as a diagnostic method for UTI or non-invasive VUR monitoring should take into consideration the patient's history of UTI regarding cut-off values.

uNGAL does not seem to be a protective factor and low values do not seem to be a predictive diagnostic tool for pediatric UTI.

Further research is required to establish specific situations in which uNGAL may be useful and to identify the best cutoff values. Further research should also focus on differentiating lower UTI from acute pyelonephritis, benefits of evaluating plasma/serum or urinary NGAL values and extending the number of patients included for better statistical value.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

INSTITUTIONAL REVIEW BOARD STATEMENT

The study was conducted in accordance with the Declaration of Helsinki and approved by the Ethics Committee of "Gr. T. Popa" University of Medicine and Pharmacy of Iasi no 8753/28 May 2020 and also by the Ethics Committee of "Sf. Maria" Emergency Clinical Hospital for Children no. 5075/17 February 2021.

INFORMED CONSENT STATEMENT

Informed consent was obtained from all subjects involved in the study.

DATA AVAILABILITY STATEMENT

The data used to support the findings of this study are available from the corresponding author upon request.

PATHOLOGICAL FEATURES IN PATIENTS WITH SEPSIS - AN AUTOPSY STUDY (Abstract) **Background and aim**: Our study aims to evaluate the etiologic profile of lesions and morphologic changes identified in the pathology generating sepsis, and to establish the lesion pattern based on necropsy examination in correlation with relevant clinical and microbiological data. **Materials and methods:** The study group included 100 patients with a clinical diagnosis of sepsis who had died, of whom 41 required autopsies. **Results:** The sepsis was confirmed after completing macroscopic and histological examination of the organs during the autopsy. 18 patients (36.58%) had a severe septic pulmonary involvement, the macroscopic diagnosis of death for 15 of them being bronchopneumonia (83.33%). For 8 patients (19.51%), the septic injury was localized at meningocerebral level, another 4 patients presented intimal valvular injuries, sustaining the diagnosis of infectious endocarditis. The most common non-specific lesions were congestion of red pulp of spleen (85.36%), severe cerebral (78.04%) and pulmonary edema (58.53%), and disseminated intravascular coagulation syndrome (51.21%). **Discussion:** The autopsy confirmed a heterogeneity of specific and non-specific lesions, and no general lesion profile could be drawn. Antibiotics are the mainstay of sepsis therapy. However, antibiotics failed to control the main outbreak of infection, with subsequent sepsis leading to death. **Conclusion**: The identified pathological features delineated the landmarks of the septic lesion within the batch, emphasizing the severity of the single or associated lesions. **Keywords:** SEPSIS, AUTOPSY, PATHOLOGICAL LESIONS.

INTRODUCTION

Sepsis is a syndrome characterized by a generalized exaggerated and unbalanced reaction to infection. The patient's response is determined by the pathogen characteristics: species, pathogenicity, virulence, microbial load, and by the host characteristics: age, gender, genetic predisposition, comorbidities, exposure and immunologic status (1, 2). The septic process is defined as the result of systemic immune reactivity initiated at a primary site of infection, commonly documented as the lungs, then the abdominal cavity, urinary tract, followed by soft tissues and blood (3).

The etiology of septic syndrome is characterized by an evident heterogeneity,

most frequently identified gram-positive infectious agents: *Staphylococcus aureus, Streptococcus pneumoniae* and gram-negative infectious agents: *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa* and *Enterococcus sp.*, respectively (2). Lately, fungal species have been identified increasingly frequently (3).

Due to the complexity of the disease, which makes it very difficult to diagnose and apply the most appropriate treatment, sepsis is one of the leading causes of death (1, 3, 4). Sepsis is becoming a public health issue due to the dramatic increase in its incidence year after year (5). The post-mortem diagnosis is also difficult due to the incomplete clinical data available to the pathologist prior to the necropsy, especially due to the short duration of hospitalization. In addition, it is not uncommon for the pathologist to identify new localizations of the infectious process that he adds to the pathogenic mechanism, which further supports the need for a necropsy examination that complements the clinical diagnosis (6, 7).

Our study aims to evaluate the etiologic profile of lesions and morphologic changes identified in the pathology generating sepsis, and to establish the lesion pattern based on necropsy examination of patients to elucidate the mechanism of thanatogenesis as precisely as possible in the sense of the general trend of using post-mortem information in clinical practice.

MATERIAL AND METHODS

Study settings

We conducted a retrospective study (01.01.2018 - 31.12.2023) evaluating medical and autopsy records. A total of 647 deaths in patients with a clinical diagnosis of sepsis were recorded during the 6-year period at "Sfanta Parascheva" Clinical Hospital of Infectious Diseases, Iasi. Deaths caused by sepsis in patients with diabetes mellitus (135 cases), arterial hypertension (258 cases), cancer (147 cases), or those requiring forensic autopsy (7 cases) were excluded from this study. Thus, we selected a group of 100 patients, of whom only 41 required post-mortem examination to clarify the final diagnosis. The medical records, the autopsy protocols, and the histopathological reports were consulted, from which the following data were extracted: age, gender, duration of hospitalization, associated etiologic agent(s), affected organ and/or systems, starting site, and the disease that caused the evolution to sepsis and the patient's death.

Autopsy protocol

Macroscopic examination

It included general macroscopic examination of the body and organs, in situ and outside the body, with evaluation of external and sectional appearance of internal organs, including brain, lungs, heart, liver, spleen, pancreas, small and large intestines, bladder, kidneys, and internal genitalia for visible septic foci. Representative lesions identified at the macroscopic level were collected for the histopathological exam.

Histopathological exam

After fixation in 10% neutral buffered formalin for 24-48 hours, tissue fragments were harvested, primary processed and embedded in paraffin. The paraffin blocks were sectioned (3-4 microns thick), and sections were stained with standardized stain Hematoxylin-Eosin and special stains such as: Periodic acid-Schiff (PAS), Grocott's methenamine silver stain (GMS).

The slides were reanalyzed by two independent pathologists to confirm the histopathologic characteristic lesions of sepsis based on data published in the literature (7, 8, 9).

Ethical Considerations The study was approved by the Institutional Ethics Committee in keeping with the principles of the Declaration of Helsinki. Data was collected anonymously from the medical records without active patient participation.

Statistical Analysis. Statistical data were processed using *SPSS version 29.0* software. Means and standard deviations were calculated for continuous variables, while absolute values and percentages were calculated for categorical variables. The group comparisons were obtained using the Chi-squared test (χ^2) and the Fisher correction if necessary. Comparisons were considered as statistically significant when p values were < 0.05.

RESULTS

General characterization of the study group

In the study group, the age of the patients ranged from 24 days to 98 years with a mean value 67±12 SD years. We noted a more frequent involvement of male patients (57/57%) compared to female patients (43/43%); 51 patients (51%) were from urban areas and 49 patients (49%) from rural areas (tab. I).

TABLE I.
Characteristics of the study group

Baseline characteristics	Units	n (%)
Male sex	n (%)	57 (57)
Age	years	67±12DS
Urban	n (%)	51 (51)
Source of infections	n (%)	
Lungs		40 (40)
Urinary tract		18 (18)
Skin		17 (17)
Abdomen		12 (12)
Central Nervous System		9 (9)
Heart		3 (3)
Pathogens		63 (63)
Gram-positive alone		13 (20.63)
Gram-negative alone		24 (38.09)
Fungal alone		1 (1.58)
Viral alone		3 (4.71)
Mixed organisms		22 (43.92)
Double		17 (26.98)
Triple		4 (6.34)
More than triple (5 agents)		1 (1.58)
Septic shock		8 (8)

Etiopathogenic profile

When assessing the etiology of sepsis, the pathogen was identified in only 63 patients (63%). Therefore, we refined the analysis of the etiopathogenic profile by separately reporting the subgroup of 63

patients in whom the pathogen was confirmed during hospitalization before death.

A total of 18 different etiologic agents were identified, including all major classes of infectious agents, such as gram-positive bacteria (*Staphylococcus aureus, Streptococcus pneumoniae, Streptococcus agalatiae, Enterococcus faecalis* and *Clostridioides difficile*), gram-negative bacteria (*Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Neisseria meningitidis, Morganella morgani, Enterobacter, Proteus mirabilis, Proteus vulgaris,* and *Acinetobacter baumannii*), viral agents (*Influenza virus, Measles virus*), and fungal agents (*Aspergillus, Candida albicans*).

Forty-one of the patients (65.08%) presented a single pathogen, the other 22 patients (34.92%), presenting multiple associations of germs, respectively two pathogens (17 cases - 26.98%), three pathogens (4 cases - 6.34%) and one case (1.58%) with 5 pathogens simultaneously (tab. I).

Pathological profile

Among the 100 patients included in the study, 41 required the completion of the clinical diagnosis by establishing a final post-mortem diagnosis for the evaluation and refinement of the clinical data (tab. II).

TABLE II.

Distribution of primary septic foci of necropsied cases in relation to the affected system:

System	No. of cases (n)	Percentage (%)
Central Nervous System	8	19.51%
Respiratory System	18	43.90%
Heart	4	9.75%
Renal System	1	2.43%
Gastrointestinal System	1	2.43%
Other (Skin, Soft Tissue)	1	4.87%
Septic Shock/ Multiple organ failure	8	17.07%
Total	**41**	**100%**

The patients had short periods of hospitalization (less than 24 hours - 12 cases, less than 48 hours - 13 cases, between 48 and 96 hours - 16 patients) - meaning a limited time to compile a complete paraclinical picture.

Macroscopic features

Following the macroscopic examination during the autopsy, a diagnosis of death from septic shock which induced a multiple organ failure was established for 8 (19.51%) patients.

In these cases, no obvious macroscopic septic foci to a single organ were identified, instead multiple non-specific systemic lesions associated with sepsis were documented, namely: skin petechiae, pericardial petechiae, medullary-adrenal hemorrhage, acute erosive gastritis, septic muddy spleen and ischemic lesions of kidneys. A particular aspect was observed in two of the patients who, on microscopic examination, had associated focal lesions of myocardial necrosis - acute myocardial infarction.

For eight patients (19.51%), the septic injury was localized the meningocerebral site: a massive diffuse edema with trans

tentorial hernia and purulent deposits at the meningeal level, lesions specific for diagnosis of meningoencephalitis. Three patients had associated well-defined areas of necrosis, an appearance highly suggestive of encephalitis with multiple brain abscesses.

Eighteen patients (36.58%) had a severe septic pulmonary involvement, the macroscopic diagnosis of death for 15 of them (83.33%) being bronchopneumonia. In 7 of these 15 cases, the bronchopneumonia occurred in the context of a lobar pneumonia, 9 of the patients presenting massive pleural effusion (>250 ml of purulent fluid) and pleural lesions of pleurisy. On background, 10 of these patients had specific lesions to a chronic bronchopneumopathy (emphysema and chronic bronchitis) and two of them presented old fibrous cavitary lesions suggestive of sequelae of tuberculosis. Half of the patients had associated micro thrombotic lesions in the small and medium blood vessels, some developing necrotic alveolar lesions around, highly suggestive of areas of recent pulmonary infarction. In the other 3 cases with macroscopic lung injuries, the lesions were viral type, with atypical interstitial localization. In two of these cases, the viral etiology was identified using molecular tests (RT-PCR test positive for type A influenza), the third case had a measles etiology.

Four patients presented intimal valvular injuries, sustaining the diagnosis of infectious endocarditis, with the identification in two cases of septic vegetations adhering to the mitral valve, in one case at the aortic valve level and in another case of perivalvular septic lesions, with the development of an abscess at the level of the metallic prosthetic aortic valve. One patient presented, in the context of *Clostridioides difficile* infection typical lesions of pseudomembranous colitis. Another patient presented macroscopically, in the context of *Staphylococcus aureus* infections, an acute renal abscess that completely affects the lower pole of the right kidney; on microscopic examination, the lesion was purulent.

Only one patient among those hospitalized with the clinical diagnosis of sepsis, who died less than 24 hours after admission, presented macroscopic lesions suggestive of the diagnosis of Baker I aortic dissection; the macroscopic diagnosis was later confirmed microscopically.

The autopsy results indicated a degree of concordance between the clinical and post-mortem diagnosis of 97.56%.

Microscopic features

The microscopic examination allowed the identification and description of the histopathological characteristics, to confirm the macroscopic diagnosis formulated for the establishment of the causes of death. Tables III, IV and V shows the specific and non-specific tissue lesions in the context of the septic process.

The most common non-specific lesions associated with septic sites were congestion of the red pulp of the spleen (85.36%) macroscopically described by a muddy appearance, reduced consistency, followed by moderate to severe cerebral edema (78.04%), with flattening of the outline, deletion of cerebral gyri and reduction the importance of tissue consistency and pulmonary edema (58.53%), renal hypoxia or acute hemorrhagic gastritis. These lesions were associated with other non-specific findings that indicated a process of affecting the coagulation phenomena, namely disseminated intravascular coagulation syndrome (51.21%) (micro thrombosis, skin petechiae, serous petechiae) (tab. V). The images in figures 1-6 illustrates microscopic lesions relevant for substantiating the diagnosis of sepsis.

TABLE III.

Histopathological lesions identified in the central nervous system and lung

Central Nervous System (n = 8)	Lung (n = 18)
Perineural edema (n = 8)	Pneumonia (n = 7)
Perivascular edema (n = 8)	Bronchopneumonia (n = 15)
Neural necrosis (n = 4)	Lung abscess (n = 3)
Septic thrombi (n = 8)	Pulmonary TB (n = 2)
Reactive gliosis (n = 8)	Pulmonary edema (n = 18)
Focal necrosis (n = 3)	Intrapulmonary hemorrhage (n = 7)
Abscess (n = 3)	Leucocytes alveolitis (n = 10)
	Microthrombi (n = 9)
	Pulmonary necrosis (5)
	Interstitial pneumonitis (3)
	Pleurisy (n = 9)
	Diffuse alveolar damages (11)

TABLE IV.

Histopathological lesions identified in heart, renal system and gastrointestinal system

Heart (n = 4)	Renal System (n = 1)	Gastrointestinal System (n = 1)
Cardiomyocytes necrosis (n = 2)	Acute tubular necrosis (n = 1)	Gangrene (n = 1)
Interstitial edema (n = 1)	Septic thrombi (n = 1)	Pseudomembranous colitis (n = 1)
Myocarditis (n = 1)	Renal abscess (n = 1)	Microthrombi (n = 1)
Endocarditis (n = 1)	Pyelonephritis (n = 1)	
Interstitial mononuclear cells (n = 2)	Bacterial colonies (n = 1)	
Septic emboli (n = 2)	Septic thrombi (n = 1)	

TABLE V.

Histopathological non-specific lesions

Non-specific lesions	No. of patients	Percentage (%)
Spleen		
Splenitis	2	4.87%
Red pulp congestion	35	85.36%
White pulp atrophy	7	17.07%
CNS		
Cerebral edema	32	78.04%
Lung		
Pulmonary edema	24	58.53%
Intravenous leukostasis	12	29.26%

Non-specific lesions	No. of patients	Percentage (%)
Heart		
Interstitial edema	5	12.19%
Epicardial hemorrhages	2	4.87%
Pericarditis/myocarditis	4	9.75%
Kidney		
Interstitial inflammation	14	34.14%
Focal necrosis	12	29.26%
Bacterial colony	1	2.43%
Liver		
Intrasinusoidal leukostasis	15	36.58%
Portal inflammation	9	21.95%
Focal necrosis	8	19.51%
Stomach		
Acute necrotizing gastritis	25	60.97%
Diffuse lesions		
Microthrombosis	21	51.21%

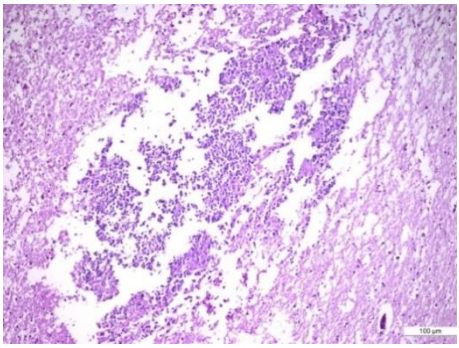

Fig. 2. Septic-pyemic micro abscess in the brain, HE, x10

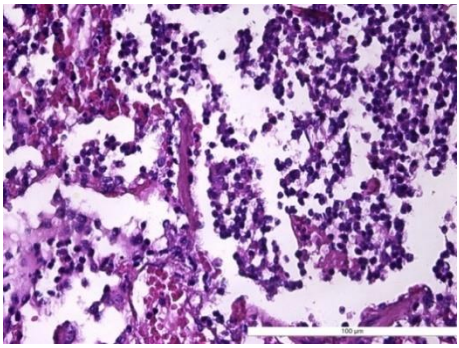

Fig. 3. Hyaline membranes covering the alveolar epithelial layer in a case of septic acute respiratory distress syndrome, HE, x40

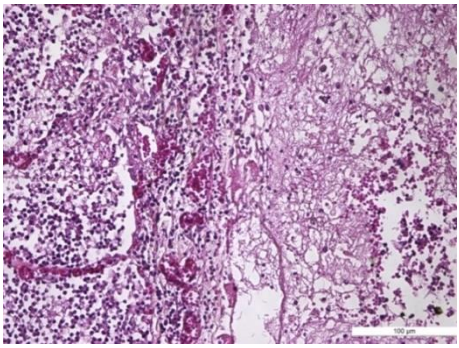

Fig. 4. Detail. Fibrinous pleurisy, HE, x20

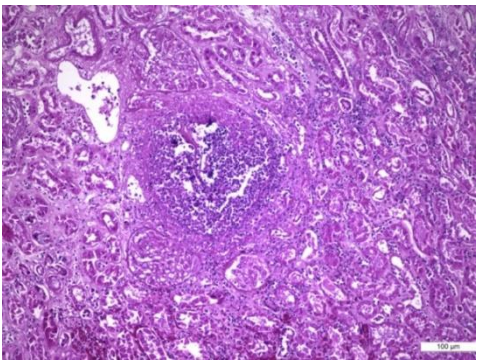

Fig. 5. Renal abscess, HE, x10

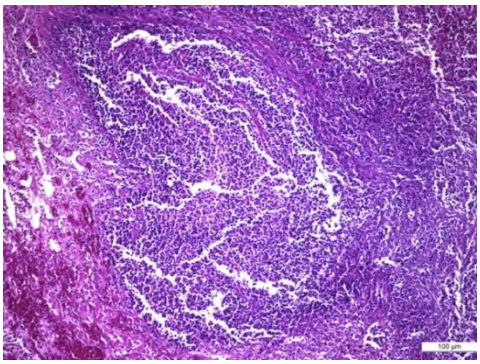

Fig. 6. Renal abscess, HE, x10

The most common microscopic findings that contributed to death were bronchopneumonia (88.33%) (figure 3), acute respiratory distress syndrome (figure 3), pulmonary edema (58.53%) and disseminated intravascular coagulation syndrome - coagulation/microthrombi (51.21%), to which are added edema and brain lesions (78.04%) (figs. 1, 2).

A statistically significant difference was identified between the primary septic site identified clinically versus post-mortem ($p = 0.0059$), with the obvious predominance of pulmonary lesions in general but with a significant contribution of renal and skin lesions.

DISCUSSION

The study made it possible an overview of the etiological profile of sepsis and the morphological changes identified in the pathology generating sepsis, in a group of patients who died of sepsis at "Sfanta Parascheva" Clinical Hospital of Infectious Diseases, Iasi.

According to the literature, sepsis is caused by gram-positive, gram-negative pathogenic bacteria and fungi (10). The main gram-positive pathogens are staphylococci (*Staphylococcus aureus* and *Staphylococcus coagulase-negative*) and streptococci (*Streptococcus pyogenes*, *Streptococcus viridans*, *Streptococcus pneumoniae*), and the main gram-negative pathogens are represented by *Escherichia coli*, *Klebsiella pneumoniae* and *Pseudomonas aeruginosa* (2). The results of our study are consistent with these data.

Regarding the distribution of sepsis cases by gender, we recorded more male patients (57%). The literature supports male predominance. This finding can be explained by the fact that the concentration of anti-inflammatory mediators is generally higher in females (11).

Following the microscopic examination, it was possible to validate the lesions described macroscopically. The results of the microscopic examination indicated a degree of concordance between the macroscopic and the microscopic diagnosis of 100%, the microscopic one improving the description of the physio pathological substrate of the diseases, a fact that supports the "gold standard" value of the microscopic morphology, in establishing the final post-mortem diagnosis.

The most striking finding of this analysis was that about 80% of all analyzed patients still had a septic focus at autopsy.

It can be argued that the detection of an infectious focus can be expected in patients who die early during sepsis. However, even in patients who were admitted to Intensive Care Unit for sepsis and treated for 7 days, the incidence of a continuous septic focus at autopsy was approximately 90%. Even though targeted antibiotics are the mainstay of sepsis therapy (12, 13), they failed to control the main outbreak of infection, with subsequent sepsis leading to death (14).

The patients included in this study were treated at "Sfanta Parascheva" Clinical Hospital of Infectious Diseases, Iasi - a tertiary healthcare center that receives a high volume of patients with highly complex infectious diseases, especially pulmonary, urinary, cerebral and terminal diseases. Not surprisingly, acute respiratory failure has been a leading cause of morbidity and mortality over the past 6 years (15, 16). Histologically, lung damage was correlated to the increased permeability of the alveolar capillary membrane, which leads to edema, protein exudates, the formation of hyaline membranes, congestion and extensive alveolar hemorrhage, aspects also described in other studies (17, 18). Another interesting finding of this study is that cerebral edema was seen in nearly 80% of patients who died of sepsis. Although only 8 of these patients (19.51%) were hospitalized for a cerebral pathology, with signs of meningeal irritation present, the necropsy examination revealed diffuse cerebral edema present in 32 (78.04%) of the 41 cases, four times more many. It is known that severe arterial hypotension associated with septic shock can cause cerebral hypoperfusion, thus inducing cerebral edema - recent evidence suggesting that the pathophysiological mechanism of septic delirium may include not only functional but also anatomical components (19,20). In the rest, the brain lesions identified were specific to the infectious etiology, complicating even to the formation of brain abscess areas (21). In our study, the most frequent cardiac pathology was the infectious endocarditis macroscopically objectified by the endocardial lesions, and the vegetative formations adhering to the valvular surface. The tropism of the infectious lesion on the prosthetic valve (22) was certified by an aortic perivalvular abscess, present in one of the patients included in the study. In addition, the ubiquitous myocardial ischemia in patients with sepsis, documented in the literature (23), was supported by areas of acute ischemic myocardial necrosis identified in two of the patients comprised in the study group. At the renal level, sepsis caused the installation of non-specific lesions, but it is worth noting the identification of multiple abscessed lesions against the background of acute tubular necrosis and perivascular microhemorrhages. Current concepts about renal failure in sepsis state that the exact onset of renal injury in sepsis remains unknown (24). Furthermore, it was considered that patients presenting with sepsis should be suspected of acute renal failure and, conversely, those presenting with acute renal failure should also be suspected of sepsis (24). Despite the small number of patients analyzed in our study, we should note the polymorphism of the renal microscopic lesions, which leads us to think of a serious, irreversible damage to the renal structure. Fortunately, advances in the understanding of the pathophysiological mechanisms of renal sepsis have offered the prospect of potential new therapies. However, effective and specific interventions for the prevention and treatment of acute renal

failure identified in a septic context are still missing (24).

A statistically significant difference ($p = 0.0059$) between the clinical versus morphological primary septic site was obtained - with the obvious predominance of pulmonary lesions and a significant contribution of renal and skin lesions. We noted a clinical overdiagnosis of renal lesions - indicating, as in the literature, that the paraclinical investigations do not always correlate with the degree of morphological lesions (24). On the other hand, liver damage sets in quite early, remaining subclinical for a longer time, considering the reactive, non-specific lesions identified in approximately 20% of the necropsied cases, without being correlated with the paraclinical data that did not signal any degree of liver failure.

The skin lesions were also frequently considered as the initial clinical site, but the autopsy most often highlights another primary lesional substrate, the skin site being, usually, the result of secondary dissemination.

CONCLUSIONS

The reported pathological features delineate the landmarks of septic lesions within the batch, emphasizing the severity of the single or associated lesions and interfering with the clinicians' efforts to stop the irreversible course of this condition towards death. This idea supports the value of the presented macroscopic and microscopic data, by the heterogeneity of the lesion profile corresponding to sepsis. Given the small number of studies published in the main body of the literature focusing on the pathological changes present at autopsy in deceased patients with sepsis, our data can be integrated into the clinical approach by reference to the etiological agent or therapeutic monitoring, respectively.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

COMPUTED TOMOGRAPHY IMAGING IN POST-SURGICAL SURVEILLANCE OF THORACIC AORTA REPAIR (Abstract): Thoracic aorta surgery is essential for managing life-threatening conditions such as acute aortic syndromes and thoracic aortic aneurysms. Postoperative complications are increasingly detected due to advancements in imaging and surgical techniques, necessitating precise imaging protocols to differentiate true complications from mimics. **Materials and methods:** We conducted a retrospective study at the Institute for Cardiovascular Diseases Iași, analyzing 24 patients who underwent thoracic aorta surgery and subsequent CT imaging between November 2023 and December 2024. CT protocols included unenhanced, arterial, and late-phase acquisitions with ECG-gated imaging. Data on demographics, comorbidities, surgical indications, and procedures were statistically analyzed. **Results:** The cohort (79.16% male, mean age 54.83 years) presented aneurysms (38.46%) and dissections (34.6%) as primary surgical indications. Hypertension was the most prevalent comorbidity (66.66%). Common procedures included the Bentall procedure (29.62%) and thoracic endovascular aortic repair (37%). Complications were identified in 54.16% of cases, including pseudoaneurysms, intramural hematomas, and endoleaks. Symptomatic patients had a higher detection rate, but 50% of asymptomatic individuals also demonstrated complications. Reintervention was required in 16.66% of cases. **Conclusions:** CT imaging plays a pivotal role in postoperative surveillance, providing critical insights into complications and mimics. Optimized imaging protocols, including ECG-gated acquisitions and delayed-phase imaging, enhance diagnostic accuracy. Routine follow-up imaging is essential, even for asymptomatic patients, to guide timely interventions and improve outcomes in thoracic aortic surgery. **Keywords:** THORACIC AORTA SURGERY, COMPUTED TOMOGRAPHY IMAGING, THORACIC ENDOVASCULAR AORTIC REPAIR, POSTOPERATIVE COMPLICATIONS.

INTRODUCTION

Thoracic aorta surgery is a cornerstone in managing life-threatening conditions, its main indications being represented by acute aortic syndromes (AAS) and thoracic aortic aneurysms (TAAs) (1, 2). AAS defines a spectrum of life-threatening conditions characterized by damage to the aortic wall induced by similar pathophysiological mechanisms, often sharing overlapping clinical presentations and diagnostic and therapeutic strategies. This spec-

trum encompasses acute aortic dissection (AAD), intramural hematoma (IMH), penetrating aortic ulcer (PAU), aortic pseudoaneurysm, and traumatic aortic injuries (TAI) (3, 4).

While classic open surgical techniques remain standard for ascending aorta repair, aortic arch management has evolved with advanced open and endovascular approaches, often combined to enable more complex and extended anatomical repairs. Surgical ascending aorta repairs associating replacement of the aortic valve (with either a mechanical or biologic valve) can be done with a supracoronary ascending aorta graft (Wheat procedure, not requiring coronary reimplantation) or by employing a composite artificial graft with coronary reimplantation (Bentall and Cabrol procedures). Valve-sparing techniques include the supracoronary replacement of the ascending aorta usually with a synthetic (Dacron) graft, the Yacoub procedure and the David-valve sparing technique and its derivatives. Aortic arch repairs are often performed alongside ascending or descending aorta repairs, utilizing techniques such as hemiarch repair, "island patch" technique, and hybrid aortic arch approaches (5,6). For pathologies of the descending thoracic aorta, thoracic endovascular aortic repair (TEVAR) represents the primary interventional treatment modality, with open surgical repair reserved for patients presenting with anatomies unsuitable for endovascular approaches (7).

Surgical techniques for thoracic aorta repair often result in characteristic computed tomography (CT) imaging appearances that may resemble complications. Accurate interpretation requires awareness of these techniques, understanding the clinical contexts in which they are employed, and familiarity with the typical locations and imaging features of such mimics. For example, structures like coronary buttons, felt buttresses (pledgets and rings), occluded coronary bypass grafts, or debranching grafts may mimic pseudoaneurysms. Similarly, perigraft hematomas, seromas, or hemostatic agents can resemble perigraft abscesses, while graft kinks, elephant trunk or reverse elephant trunk procedures, and the Cabrol procedure may mimic aortic dissection. Recognizing these mimics is crucial to avoid unnecessary surgical consultations, follow-up imaging, or revisions. Optimized imaging protocols play a vital role in distinguishing true complications from their mimics. True complications of thoracic aorta repairs encompass a broad spectrum, including infections (e.g, perigraft abscess, infectious pseudoaneurysm, endocarditis, sternal dehiscence, or osteomyelitis), non-infectious prosthetic material failure (e.g., pseudoaneurysms at anastomosis or cannulation sites), hemorrhage, endograft-related issues (e.g., endoleaks, stent migration, collapse, or false lumen deployment), and pathology involving the adjacent aorta (e.g., aneurysms, aortic dissection, or intramural hematomas) (5, 8, 9, 10).

As the number of patients undergoing thoracic aorta repair increases (due to ageing population and surgical technique improvement) and imaging techniques continue to advance, the detection of complications has become more frequent. These complications, often associated with significant morbidity, may remain clinically silent, underscoring the essential role of CT imaging in patient follow-up protocols. The aim of this study is to evaluate the role of CT imaging in the post-surgical surveillance of thoracic aorta repair, with a focus

on identifying complications, distinguishing between true complications and mimics, and highlighting the clinical implications of these findings in guiding patient management.

MATERIALS AND METHODS

We conducted a retrospective, single-center study on the patients who underwent CT examinations at the Institute for Cardiovascular Diseases Iași between November 2023 and December 2024. The inclusion criterion was the history of thoracic aorta surgery, as mentioned by the CT reports and confirmed by the identification of surgical thoracic aorta prosthetic material on the acquired images. In the aforementioned time frame, from the total of 2,819 CT reports reviewed, we identified 24 patients eligible for this study, who were scanned either as a part of their regular post-operative follow-up or due to the appearance of signs and symptoms suggestive of a potential complication.

The images were acquired using a 256-slice dual-source CT-scanner, using slice thickness reconstructions of 1 mm within a coverage from the thoracic inlet to the femoral arteries. For the optimal assessment of the aortic valve, root and proximal ascending aorta retrospective electrocardiographic (ECG) gating was employed. The standard protocol included unenhanced and arterial phase (employing the "Bolus-tracking" technique) acquisitions, late phase acquisitions being used only in selected cases. The iodinated contrast material was administered intravenously (preferably through a right antecubital vein) at an injection rate of 5 mL/sec, followed by a saline chaser, the total dose being adjusted according to the patient`s body weight.

Data regarding patients' demographics, comorbidities, surgical indication and procedures were collected by consulting the electronic database of the hospital, then introduced into a *Microsoft Excel* database and statistically analyzed.

RESULTS

The study cohort predominantly consisted of male patients, accounting for 79.16% of the total population. Patient ages ranged from 18 to 76 years, with a mean age of 54.83 years. The average age for male patients was 52.79 years, while female patients had a higher mean age of 63 years.

Cardiovascular comorbidities were common in the study group, with essential arterial hypertension observed in 66.66% of patients. Other notable cardiovascular conditions included bicuspid aortic valve (12.5%) and Takayasu arteritis (4.16%). Chronic heart failure was present in 25% of cases, evenly distributed between those with preserved ejection fraction and those with mildly reduced ejection fraction. Additionally, chronic coronary syndrome (12.5%) and atrial fibrillation (20.83%) were frequently identified. The young patients from our study associated systemic disorders such as Marfan syndrome and Turner syndrome, known for their induced predisposition for aortic dilatation and/or dissection. Respiratory comorbidities included obstructive sleep apnea (12.5%) and chronic obstructive pulmonary disease (4.16%). Metabolic disorders were also prevalent, with dyslipidemia identified in 62.5% of patients, chronic kidney disease in 12.5%, and type 2 diabetes mellitus in 8.33%. Three patients presented with oncologic or hematologic conditions: one case each of bronchopulmonary carcinoma, chronic lymphocytic leukaemia, and myel-

odysplastic syndrome (tab. I).

TABLE I.
Associated comorbidities and their prevalence in the study group

Associated comorbidity	Prevalence
Essential arterial hypertension	66.66%
Chronic heart failure	25%
Atrial fibrillation	20.83%
Chronic coronary syndrome	12.5%
Bicuspid aortic valve	12.5%
Marfan syndrome	12.5%
Turner syndrome	4.16%
Takayasu disease	4.16%
Obstructive sleep apnea syndrome	12.5%
Chronic obstructive pulmonary disease	4.16%
Dyslipidemia	62.5%
Chronic kidney disease	12.5%
Type 2 diabetes mellitus	8.33%

The primary indications for thoracic aortic interventions in the study cohort included thoracic aortic dissection in 34.6% of cases, with Stanford A dissections accounting for 23.07% and Stanford B for 11.53%. Pseudoaneurysms were observed in 19.23% of cases, distributed as 7.69% in the ascending aorta, 3.84% in the aortic arch, and 7.69% in the descending aorta. Aneurysms represented the most common indication, affecting 38.46% of patients, with 26.92% involving the ascending aorta and 11.54% the descending aorta. Less frequent indications included infectious endocarditis (3.84%) and aortic coarctation (3.84%). Notably, 71.42% of patients undergoing ascending aortic aneurysm repair presented with severe aortic valve dysfunction necessitating valvular replacement. The surgical techniques employed varied widely, with the Bentall procedure performed in 29.62% of cases and TEVAR in 37%, half of which included debranching procedures. Other approaches included the Wheat procedure (3.7%), Tirone-David procedure (11.11%), and ascending aorta replacement with Dacron grafts (14.8%). Open surgical repair of the thoracic aorta was performed in one patient with anatomy unsuitable for TEVAR (3.7%) (fig. 1). Aorto-coronary bypass for myocardial revascularization was concurrently conducted in two cases.

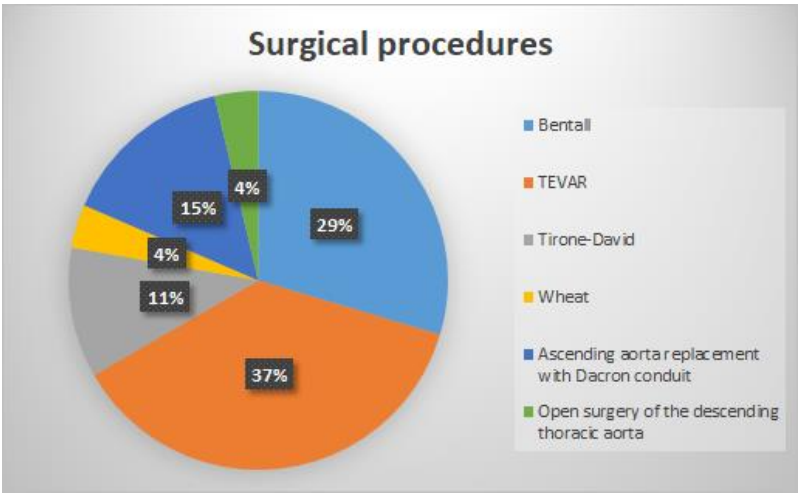

Fig. 1. Graphical representation of the surgical procedures used in the study cohort.

In terms of follow-up imaging, 66.66% of patients were asymptomatic and underwent CT scans as part of routine postoperative monitoring. A further 16.66% were scanned during the immediate postoperative period (within two weeks of surgery) as part of standard post-surgical checks. The remaining 16.66% were scanned due to symptoms suggestive of complications, including fever, chest pain, sudden-onset dyspnea, or syncope. Excluding immediate postoperative checks, the mean interval between surgery and follow-up imaging was 42.6 months.

Complications related to thoracic aortic interventions were identified in 54.16% of cases. These included perianastomotic pseudoaneurysms (12.5%), de novo dissection flaps (8.33%), intramural or periprosthetic hematomas (12.5%), surgical wound dehiscence (8.33%), and issues involving debranching conduits such as thrombosis or anastomotic stenosis (8.33%). Other complications included endoleaks (4.16%), hemopericardium (4.16%), and prosthetic material displacement (4.16%). Half of the asymptomatic patients undergoing routine follow-up imaging, as well as half of the patients scanned as an immediate postoperative check demonstrated surgery-related complications. Among symptomatic patients, CT imaging confirmed the presence of surgical complications in nearly all cases, with the sole exception being a patient in whom acute pulmonary embolism was excluded (fig. 2). 16.66% of the cases included in the study exhibited imaging findings necessitating surgical reintervention (the minor revision of the surgical wound dehiscence and the drainage of the hemopericardium not included). All the required reinterventions were successfully performed, except in one patient with infectious endocarditis complicated by a perivalvular abscess, rupture of the mitro-aortic continuity, and prosthetic material breakdown. This patient succumbed shortly after imaging confirmed the diagnosis.

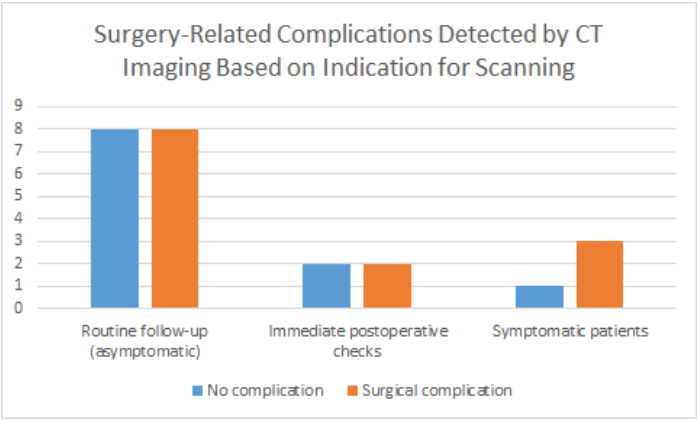

Fig. 2. Postsurgical complications detected by CT imaging based on the indication for scanning.

DISCUSSION

In our cohort, aneurysms and dissections emerged as the predominant indications for thoracic aortic interventions, accounting for over 70% of cases, both of them encountered with a higher prevalence in males. The ascending aorta was the predilect zone for the development of the aneurysmal dilata-

tion, and Stanford A dissections were more frequently encountered than Stanford B, reflecting a distribution consistent with existing literature (11, 12, 13).

Systemic arterial hypertension was the most prevalent comorbidity in our study cohort, consistent with its established role in the literature as the primary risk factor for thoracic aortic aneurysms and the most common contributor to aortic dissection (14). Heritable thoracic aortic conditions (HTAD), bicuspid aortic valve (BAV), Takayasu disease and previous aortic surgeries are more commonly observed in patients under the age of 40 (15, 16). This trend was also observed in our study, where the four patients under 40 years of age undergoing surgery were diagnosed with Marfan syndrome (two cases, one with concomitant BAV), Turner syndrome (with associated BAV), and Takayasu disease. Metabolic comorbidities, especially diabetes mellitus is associated with a higher risk of surgical wound dehiscence, by delaying tissue repair, increasing the risk of infections, and reducing collagen synthesis due to hyperglycemia-induced vascular and immune dysfunction (17). Respiratory comorbidities significantly impact thoracic aortic pathology. Obstructive sleep apnea syndrome (OSAS) is an independent risk factor for aortic dissection and root dilation, while chronic obstructive pulmonary disease (COPD) increases the risk of descending thoracic aortic aneurysm rupture (2). Notably, the study's only COPD patient presented with a complicated descending thoracic aneurysm, manifesting as a pseudoaneurysm from a contained rupture.

In our cohort, the Bentall procedure emerged as a frequent intervention, reflecting its utility in addressing complex pathologies involving the ascending aorta, aortic root and aortic valve, particularly in patients with connective tissue disorders or severe aortic valve dysfunction. Similarly, TEVAR was the predominant approach for descending thoracic aorta pathologies, with half of these cases necessitating debranching to extend anatomical coverage-a testament to the growing reliance on hybrid techniques for managing extensive or anatomically challenging disease. In cases with favorable anatomy and after considering the risk of late dilatation of sinuses when spared, valve-sparing techniques were also employed. In cases of isolated dilation of the ascending tubular (supracoronary) aorta, the diseased ascending aorta was replaced with a tubular Dacron graft, with the distal anastomosis positioned immediately proximal to the aortic arch. Management strategies in AAS aligned with current guidelines, with open surgical repair being the standard for Stanford A lesions due to their proximal location and life-threatening nature, while endovascular approaches such as TEVAR were more commonly employed for Stanford B lesions, highlighting the shift towards less invasive techniques for distal aortic pathologies (18, 19, 20, 21, 22).

Various imaging modalities, including transthoracic echocardiography (TTE), transesophageal echocardiography (TOE), cardiac computed tomography (CCT), and cardiac magnetic resonance (CMR), are used for follow-up after thoracic aortic interventions, with CCT being the most commonly utilized and accessible. However, no standardized imaging protocol exists, as recommendations are primarily based on expert opinion or single-center studies. Follow-up schedules vary by surgical indication and procedure type: imaging after TAA repair occurs less frequently (usually at discharge, one year, and every five years if stable), while AAS repair involves closer monitoring (every six months in the first year, annually until year three, and every two-three

years thereafter). TEVAR requires stricter surveillance, including imaging at one month and annually for at least five years, due to a higher risk of late reinterventions and complications such as retrograde type A dissection (RTAD) (2, 23, 24). Notably, although RTAD usually occurs at the time of the index procedure, up to 31% of the cases may be diagnosed later than 3 months after the endovascular or hybrid repair, as observed in one study patient who developed RTAD one-year post-TEVAR with debranching for a pseudoaneurysm (25, 26).

The imaging protocol at our institution is designed to ensure precise postoperative evaluation by incorporating retrospective ECG-gated acquisition, non-contrast imaging, and delayed-phase imaging (60-90 seconds delay) in selected cases, alongside the standard arterial phase. ECG gating plays a crucial role in reducing motion artifacts and improving visualization of the aortic root and ascending aorta. Retrospective ECG gating, in particular, enables optimal cinematic reconstructions throughout the cardiac cycle, leading to the detection of complications such as small leaks or pseudoaneurysms, which may only be apparent during specific phases of the cardiac cycle. Initial non-contrast images are essential for distinguishing hyperdense surgical materials from pseudoaneurysms or leaks and for identifying hyperdense blood products and postoperative hematomas that may be obscured in contrast-enhanced images (fig. 3). Delayed-phase imaging is crucial for detecting endoleaks, late opacification of the false lumen in residual dissections, and complications such as inflammatory fat stranding or rim enhancement associated with infection (8, 27, 28, 29).

One of the most significant challenges for radiologists is accurately distinguishing normal postoperative findings from potentially life-threatening complications, which necessitates a thorough understanding of surgical procedures and their potential imaging mimics. Synthetic aortic grafts can be identified on noncontrast CT scans by their hyper-attenuating appearance relative to the native aorta, a feature that may be less apparent on postcontrast images due to the adjacent blood pool. Additionally, aortic grafts often display a nonanatomic configuration, being less pliable than the native aorta. Instead of a smooth, curved morphology, they tend to have a straighter shape with associated angulations, appearing more redundant than expected. These grafts may also produce folds or kinks, which can occasionally resemble a short dissection flap on axial imaging but are readily identifiable as such on coronal and sagittal reformats (5, 8). The contrasting aspects of normal aortic graft folds and the presence of a true intimal flap in a patient who developed RTAD after TEVAR associating debranching are depicted in figure 4. Pseudoaneurysms commonly arise at anastomotic suture lines and appear as saccular outpouchings of contrast extending beyond the aorta's expected contours. They may also develop at cardiopulmonary bypass cannulation sites or locations of infection or abscesses. On CT imaging, pseudoaneurysms are characterized by a communication with the aortic lumen, typically contained by the aorta or surrounding tissues. Infectious pseudoaneurysms exhibit irregular borders, may have a saccular shape with a narrow neck, are associated with inflammatory stranding, and tend to grow rapidly. In contrast, noninfected pseudoaneurysms generally lack inflammatory stranding, grow more slowly, and are located at sites of potential structural failure, such as anastomoses or cannulation sites (5). Dense felt pledgets used to reinforce anastomotic suture lines can mimic pseudoaneurysms on CT. Differentiation relies on correlation with noncontrast images and recognition of

typical locations (27, 28). The differences between felt pledgets, infectious and non-infected pseudoaneurysms are depicted in figure 3.

Thrombosis of a bypass graft used as a debranching conduit can also mimic a pseudoaneurysm if a short patent lumen persists at the ostium (8). This distinction proved crucial in a patient imaged 16 months post-TEVAR with debranching, where identifying conduit occlusion with retrograde flow through a secondary bypass graft avoided an unnecessary surgical intervention (had it been misinterpreted as a pseudo-aneurysm). Graft infections may occur at any postoperative stage, initially presenting as abnormal fluid or gas bubbles, which can be challenging to differentiate from perioperative inflammation, particularly in the early postoperative period. Delayed contrast-enhanced images are often useful for identifying rim enhancement indicative of infected peri-graft fluid or abscess formation. Advanced infections may result in pseudoaneurysms or fistulas. In the immediate postoperative setting, complex fluid and gas collections at the surgical site, including mediastinal blood products and hemostatic materials (Gelfoam© or Surgicel©), are common and often benign. Mild rim enhancement may also be normal and not indicative of infection (5, 28, 29). The timing of imaging relative to surgery is crucial for accurate interpretation of these findings.

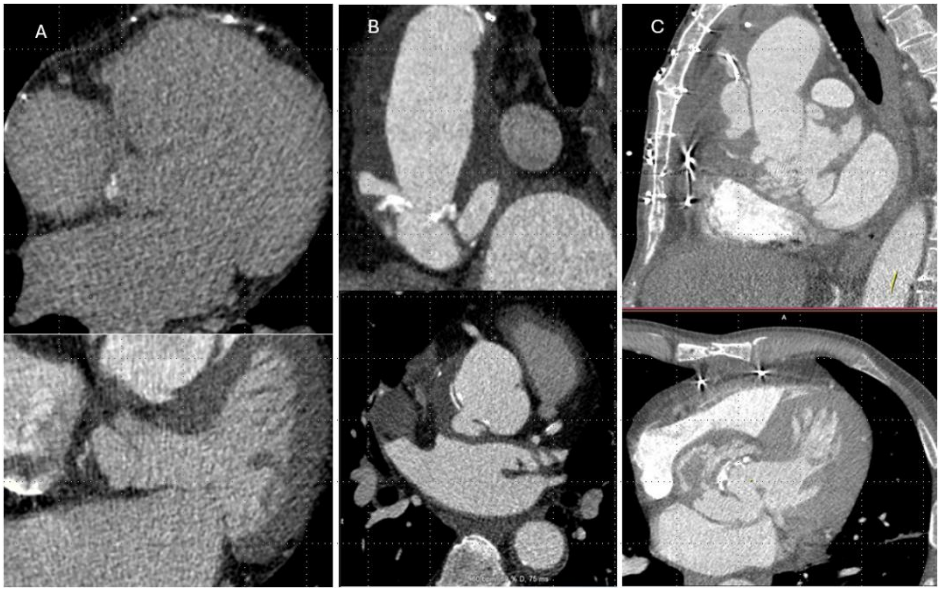

Fig. 3. A. Felt pledget in wall of the aortic root (non-coronary sinus) potentially mimicking a small pseudoaneurysm in the arterial phase (below), the confusion being avoided by the hyperdense aspect present in the non-contrast scan (above). **B.** Noninfected pseudoaneurysm in a typical location, at the proximal anastomosis, without significant stranding in the nearby tissues. Peri-graft fluid collection (seroma) with no mass effect on the ascending aorta graft. **C.** Multiple infectious, communicating pseudoaneurysms surrounding the proximal ascending aorta (with important systolic compression on the ascending aorta graft) in a patient with infective endocarditis on the prosthetic aortic valve, following Bentall procedure.

A breach is demonstrated in the mitro-aortic continuity. An epicardial cardiac stimulation wire courses through one of the pseudoaneurysm.

Fig. 4. A. Normal postoperative aspect after Bentall procedure and TEVAR associating debranching in a 42-year-old female with Takayasu disease - the normal graft folds in the axial plane are not to be confused with an intimal dissection flap (coronal and sagittal reformations are helpful in avoiding a misdiagnosis). **B.** Retrograde type A aortic dissection in a male patient one year after TEVAR associating debranching. Fortunately, the debranching conduit supplying the branches of the aortic arch originates from the true lumen.

In alignment with existing literature, the most common complications observed in the study cohort were pseudoaneurysms and TEVAR-specific complications (RTAD, type II endoleak, debranching conduit occlusion and anastomotic stenosis), particularly in cases performed under emergency conditions (2). The rate of complications necessitating re-intervention was 16.6%, closely approximating previously reported rates of approximately 10% (24). Notably, while the detection rate of complications was higher among symptomatic patients, CT imaging also identified complications in 50% of asymptomatic individuals. The critical role of CT imaging in the postoperative setting is further emphasized by its superior diagnostic capability; transthoracic echocardiography (TTE) raised suspicion of potential complications in only 15% of cases subsequently confirmed by CT.

CONCLUSIONS

This study highlights the critical role of CT imaging in the postoperative surveillance of thoracic aorta repairs, emphasizing its utility in identifying both true complications and their mimics. Complications were observed in over half of the cases, with a significant proportion detected even in asymptomatic patients, underscoring the importance of routine follow-up imaging. Advanced imaging protocols, including ECG-gated acquisitions and delayed-phase imaging, proved essential in distinguishing benign postoperative findings from potentially life-threatening conditions. Furthermore, the findings reiterate the importance of a tailored imaging approach, given the varied surgical techniques and associated imaging appearances. This study reaffirms CT imaging as an indispensable tool in guiding timely interventions, ultimately improving patient outcomes in the complex management of thoracic aortic pathology.

MEASURING ONCOLOGY PATIENT EXPERIENCE: QUESTIONNAIRE DEVELOPMENT AND VALIDATION (Abstract): The experience of oncology patients has emerged as a critical measure of care quality within the framework of a patient-centered approach to assessing health system performance. The absence of a validated instrument specific to the Romanian context restricts healthcare centers' capacity to effectuate significant enhancements. This research focused on the development and validation of a standardized instrument, the *Oncology Patient's Healthcare Experience Questionnaire* (OPEX), designed to evaluate the experiences of cancer patients. **Materials and methods:** This questionnaire was developed using a conceptual framework, which provided the foundation for creating the questionnaire items. The instrument's initial version underwent content validation with a sample of 50 patients, subsequently being administered to a larger cohort of 200 patients for psychometric analysis. The initial analysis of internal consistency yielded a Cronbach's alpha of 0.604. Following item revision, this value improved to 0.867, demonstrating enhanced reliability and validity. **Results:** The OPEX questionnaire includes 52 items grouped into seven essential dimensions of oncology care: interactions with physicians and nurses, patient information and education, hospital environment and organization, patient safety, relationships with carers, interactions with auxiliary staff, and facility infrastructure. This robust instrument, tailored to Romanian healthcare, captures oncology patients' unique experiences and improves the quality of patient-centered care. **Conclusions:** The OPEX questionnaire may serve as a reference tool for assessing patient satisfaction, providing insights into perceived care quality, identifying systemic gaps, enhancing clinical communication, personalizing interventions, and improving treatment adherence and therapeutic outcomes. **Keywords:** PATIENT EXPERIENCE, ONCOLOGY, DEVELOPMENT, QUESTIONNAIRE, VALIDATION.

INTRODUCTION

In the current landscape of healthcare, evaluating patients' experiences with the national health system has become a key component in assessing its overall performance(1). Patient experience is one of the three core dimensions of healthcare quality included in the OECD Health System Performance Framework (Organization for Economic Co-operation and Development) (2). It is also recognized as a key factor in the WHO's framework for evaluating health system performance (3). Over the past years, amid a growing shift toward patient-centered care, the experience of patients in their interactions with the healthcare system has emerged as a critical indicator of service quality (4).

In the field of oncology, where patients are confronted with complex diagnoses, intensive treatment regimens with substantial psychosocial implications, and an elevated need for multidisciplinary support (5,6), the systematic understanding and monitoring of the patient experience is of critical importance for enhancing clinical outcomes and overall patient satisfaction (7). The assessment of oncology patients' experiences not only provides valuable insights into the perceived quality of care, but also contributes to identifying gaps within the healthcare system, enhancing clinical communication, personalizing interventions, and ultimately improving treatment adherence and therapeutic outcomes (8). Patient experience measurement tools, known as Patient-Reported Experience Measures (PREMs), have been developed to capture patients' perceptions of the quality of care received. A notable example is the PREM-C, a validated instrument that assesses the experience of oncology outpatients, demonstrating high internal consistency as well as appropriate convergent and divergent validity. Additionally, the OUTPATSAT-35RT has been validated in a cohort from India, highlighting strong psychometric properties and relevance in the context of outpatient radiotherapy (9).

Although there are numerous internationally validated instruments available to assess patient satisfaction and experience in general, their adaptation to the specific context of oncology care is frequently inadequate. The duration and intensity of treatment, the ongoing relationship with the medical team, and the psychosocial challenges associated with the disease all significantly influence the needs of oncology patients (10). Therefore, the specific characteristics and priorities of this patient population may not be adequately captured by a generic instrument. Additionally, the necessity of contextualized tools that are tailored to local specificities is emphasised by the cultural and systemic divergences that exist among healthcare systems (11).

Despite the increasing emphasis on the establishment of networks of centers of excellence and the growing interest in enhancing the quality of oncology care, Romania currently lacks a national questionnaire for evaluating patient satisfaction with healthcare services. The capacity of medical providers to implement effective service improvement policies is restricted by this absence.

The aim of this study is to develop and validate a standardized, scientifically rigorous questionnaire designed to assess the experience of patients in oncology care centers across Romania. Our objective was to develop a questionnaire that assesses patients' experiences with oncology care centers. A conceptual framework was established to guide the development of the Oncology Patient's Healthcare Experience

Questionnaire (OPEX).

MATERIALS AND METHODS

Validation of the OPEX Questionnaire

The validation of a questionnaire is an essential process to ensure that the measurement instrument is both reliable and accurately assesses the intended constructs. This process encompasses several stages, from the initial development of the questionnaire to the testing and analysis of the results. The main steps undertaken in the validation of the OPEX questionnaire included:

1. Initial Development of the Questionnaire

a. Definition of Purpose and Objectives:

- The primary purpose of the questionnaire was clearly defined, along with the specific information intended to be obtained.
- Semi-structured interviews were conducted.
- The variables to be measured were identified.

b. Item Construction:

- Items (questions) were formulated to be clear, concise, and aligned with the objectives of the questionnaire.
- A mix of open-ended and closed-ended questions was used, including four-point scales and five-point Likert-type scales.

c. Expert Consultation (Focus Groups):

- Experts reviewed and validated the initial content of the questionnaire to ensure **content validity**.
- Open-ended questions enabled respondents to answer freely, facilitating the collection of qualitative data.
- Closed-ended questions, offering predefined answer options, were useful for quantitative data collection.
- Rating scales (e.g., Likert scales) allowed for measuring the degree of agreement or disagreement with specific statements.

2. Content Validity

a. Expert Evaluation:

- Experts assessed each item for its relevance and ability to accurately measure the intended variables. They also evaluated whether the items adequately covered all relevant aspects of the concept being investigated, and whether the items were clear, precise, and free from ambiguity.
- Techniques such as the **Item Content Validity Index (I-CVI)** were employed to assess the content validity of individual items during the scale development process.

b. Pilot Testing:

- The questionnaire was administered to a small sample from the target population (50 patients).
- Based on the pilot results, the clarity and relevance of the questions were assessed.
- The initial version of the questionnaire was revised, and necessary adjustments were made to improve its quality.

3. Validity and Reliability

a. Construct Validity:

- Statistical analyses, such as **factor analysis**, were used to determine whether items grouped together as theoretically expected.
- This step confirmed that the items measured the theoretical constructs

they were intended to assess.

b. Criterion Validity:

- Correlation analyses were used to evaluate **concurrent and predictive validity**, including intra-item correlations.

c. Reliability (Internal Consistency):

- The **Cronbach's Alpha coefficient** was used to assess the internal consistency of the questionnaire.
- A coefficient of $\alpha \geq 0.70$ was considered acceptable for most research purposes.

4. Administration and Data Analysis

The revised questionnaire was administered to a representative sample of 200 patients from the target population. In this phase, the reliability and validity of the questionnaire were reassessed using the collected data. Internal consistency was re-evaluated using Cronbach's Alpha for the revised version of the instrument.

5. Revision and Finalization

Based on the data analysis results, items that were found to be unreliable or invalid were revised. This process led to the development of the **final version of the OPEX questionnaire**, which demonstrated satisfactory psychometric properties.

RESULTS

The development and validation of the OPEX (Oncology Patient Experience) questionnaire involved a structured, multi-phase process encompassing three overarching stages: the development of a preliminary questionnaire, an initial evaluation of internal consistency, and final validation.

Preliminary Questionnaire Development

The design of the pilot version of the OPEX questionnaire was grounded in the Consumer Quality Index (CQI) methodology. This approach emphasizes co-creation and was implemented through active collaboration with patients, medical oncologists, oncology nurses, and psycho-oncologists.

To inform the development of the preliminary questionnaire, **50 semi-structured interviews** and **2 focus groups** were conducted between January and April 2023. Participants were recruited from the Elias Oncology Clinic (University Emergency Hospital Elias, SUUE). Interviews began with open-ended questions to explore patients' perceptions regarding the importance of various aspects of oncology care. Focus groups, facilitated by two researchers and one psycho-oncologist, involved 6 and 10 patients respectively and encouraged open discussion on improving the efficiency and quality of care at SUUE.

Inclusion criteria for participant selection were as follows:

1. Patients under the care of the clinic for at least three months.
2. Actively undergoing oncological treatment at SUUE.
3. Having a performance status appropriate for outpatient care (patients with ECOG = 4 or those hospitalized under continuous inpatient care were excluded).

Conceptual Framework Development

In the initial stage, a **conceptual framework** for the OPEX questionnaire was established through the following components:

- **A literature review** to identify relevant dimensions of the patient care experience.
- **Semi-structured interviews** aimed at identifying care aspects pertinent

to the patient population at SUUE.

- **Focus groups** that allowed participants to freely express their perspectives on enhancing the quality and effectiveness of oncology care at the center.

The protocol for semi-structured interviews included the following steps:

1. Introduction of the researcher.
2. Explanation of the study's purpose.
3. Informed consent acquisition.
4. Demographic and clinical background questions.

The interview format allowed patients to express their views on one of the **seven key dimensions** of oncology care. These domains also enabled patients to propose additional aspects not previously considered.

During the second part of the interview process, participants were asked targeted follow-up questions:

1. What would improve your experience at this medical center?
2. Which of the aspects discussed is most important to you?
3. On a scale from 0 to 10, how would you rate this aspect?
4. How would you rate the other discussed elements in terms of importance?
5. If you were the hospital director, how would you improve the hospital's conditions/medical team/infrastructure?
6. List three things you appreciate and three things you dislike about this medical center.

Structure of the Pilot Questionnaire

Based on the findings from the interviews and focus groups, the **first version of the OPEX questionnaire** was developed. It included:

- A **general section** collecting demographic and health-related data,
- **Seven sections** corresponding to key domains of the oncology care experience,
- A **final section** capturing the patient's overall evaluation of the received care.

The seven core domains included:

1. Physician-patient communication,
2. Nurse-patient interaction,
3. Patient information and education,
4. Hospital environment and organization,
5. Patient safety,
6. Interaction with family members,
7. Non-clinical staff and infrastructure.

These sections comprised a total of **38 items** (tab. I). The questionnaire concluded with five open-ended items designed to capture personal perspectives on the assessed aspects.

Item Construction Principles

Items were formulated using simple, concise, and culturally appropriate language, ensuring relevance and clarity for the target population. Each item was designed to address a single construct to maintain conceptual consistency throughout the instrument. Complex or double-barreled items (e.g., "My daily activities and mood are disturbed by my pain") were explicitly avoided, as were universally agreeable statements (e.g., "I would like to ease my pain"), which could limit response variability and diminish the questionnaire's discriminative power. This rigorous process ensured that the pilot OPEX questionnaire achieved strong content validity and laid the foundation for subsequent psychometric evaluation and final validation.

TABLE I.
The number of items in the OPEX questionnaire during the internal validation and content development phases

SECTION	OPEX		
	Semi-structured interviews	PHASE II	PHASE III
	ITEMS NUMBER		
I	10	14	14
II	7	8	8
III	7	13	13
IV	5	5	5
V	4	6	6
VI	2	2	2
VII	3	4	4
TOTAL	**38**	**52**	**52**

To ensure that the OPEX questionnaire is psychometrically robust, we applied statistical methods to assess content validity (Phase 2) (tab. II), internal validation, and to evaluate its reliability and validity (Phase 3) (tab. III). In both phases, internal consistency was evaluated, reflecting the degree to which the questionnaire items are inter-correlated and consistently measure the same construct. During the second phase of internal validation, a low Cronbach's alpha coefficient was observed (Cronbach's alpha = 0.604) (tab. III), which may be attributed to weak inter-item correlations. Items demonstrating low correlations with the total score were further analyzed and, where appropriate, were either eliminated or revised.

TABLE II.
Internal consistency analysis of the questionnaire conducted on a sample of 50 patients (Phase 2)

Since Cronbach's alpha is a function of questionnaire length, its value tends to increase with the number of items. Additionally, alpha increases when the variability of individual items is higher. Therefore, it is possible to enhance the alpha coeffi-

cient by including more interrelated items or items with greater variability. On the other hand, a very high alpha value ($\alpha \geq 0.90$) may suggest that some items in the questionnaire are redundant. In such cases, it may be appropriate to consider removing items that essentially ask the same question in different forms.

In practice, alpha simply indicates the degree to which the questionnaire is reliable for a specific population. As such, the reliability of the questionnaire was reassessed each time the instrument was administered, and Cronbach's alpha was calculated as part of the validation process. This coefficient ranges from 0 to 1, and a value below 0.7 typically indicates that certain items should be removed to improve internal consistency. The goal is to increase Cronbach's alpha above 0.7 so that the retained items are considered valid and the questionnaire more reliable. The alpha value can thus be improved by removing inappropriate or poorly correlated items. The next phase involves reprocessing the data.

Following this new iteration, items that initially had low but positive correlations with the total scale demonstrated improved correlations. Nevertheless, positively worded items with item-total correlations below 0.3 should not be retained, as they do not contribute meaningfully to the construct being measured and only serve to increase respondent burden.

A low Cronbach's alpha may result from weak inter-item correlations, and items with poor correlation to the total score should be eliminated or revised accordingly.

The **internal consistency** of a questionnaire is a statistical property that reflects the need for its "internal purity." Internal consistency is supported by two essential aspects:

1. Convergence of all items toward the targeted objective of the questionnaire. It is essential that the instrument does not include irrelevant items, as responses to such items may dilute the significance of relevant ones. These nonessential items introduce noise and can distort the overall measurement.
2. Item-level relevance, which requires a detailed examination of each item to determine its significance in relation to the construct being measured. This is typically assessed by the response rate or the proportion of meaningful responses received for each item.

In conclusion, reliability depends not only on the quality of the questionnaire's construction but also on the nature of the traits being measured. It is also crucial to know the reliability coefficient of the questionnaire to assess the degree of confidence that can be placed in its results. Furthermore, the characteristics of the population being assessed must be considered, as reliability may vary and tends to remain constant only within similar populations.

Sensitivity is another statistical quality of the questionnaire and refers to its discriminative precision, i.e., the number of categories it can define within a group. In other words, sensitivity reflects the questionnaire's ability to differentiate between individuals across a wide range. The more finely the instrument can classify respondents-while remaining aligned with real, meaningful differences-the more sensitive it is.

Standardization refers to the degree of uniformity in the administration and interpretation of the questionnaire. By definition, a questionnaire is a standardized in-

strument in three respects: content, application, and interpretation. Adherence to a clearly defined set of norms is essential for ensuring consistency across different uses.

Since all items are expected to reflect a specific attribute, they should demonstrate shared variance and correlate with one another. When each item is relevant, the instrument is said to exhibit internal consistency.

In the initial analysis (Phase II), the Cronbach's alpha coefficient was 0.604-a modest value relative to the accepted threshold of 0.70. This result indicated the need to exclude poorly performing items to improve reliability (tab. II).

The next phase involved reanalyzing and refining the questionnaire, during which items were revised, reformulated, added, or eliminated based on psychometric criteria.

Following this new iteration, items that previously had low but positive correlations with the scale were expected to show increased correlations. Nonetheless, positively worded items with item-total correlations below 0.3 should be removed, as they do not contribute meaningfully to the underlying construct and unnecessarily prolong the administration of the instrument.

After repeating the statistical analysis, a new set of results was obtained (tabs. III and IV), showing a substantially higher Cronbach's alpha. Moreover, inspection of the final column ("Alpha if item deleted") revealed that removing any individual item would not result in an alpha value higher than the one already obtained, confirming the improved internal structure of the final questionnaire.

TABLE III.

Final internal consistency evaluation of the questionnaire conducted on a sample of 200 patients (Phase 3)

Valid N: 200 (OPEX.sta)					
Summary for scale: Mean=5592.18					
Std.Dv. = 14.8269					
Cronbach alpha: 0.867207					
Standardized alpha: 0.886460					
Average inter-item corr: 0.133238					
Analysis of Variance (OPEX.sta)					
	Sums of - Squares	df	Mean - Square	F	p
Between Subjects	487.637	122	3.99703		
Within Subjects	4598.109	6642	0.69228		
Between Items	1101.340	54	20.39519	38.42504	0.00
Residual	3496.769	6588	0.53078		
Total	5085.747	6764			

The greater the number of items included at this phase, the higher the likelihood of retaining items that show stronger correlations with the overall scale, thereby achieving a higher level of internal consistency (12).

The calculated Cronbach's alpha coefficient was 0.867 (tab. III), indicating that the questionnaire is valid and demonstrates high internal consistency.

Two key indicators were analyzed:

- **Item-Total Correlation (Itm-Totl**

Correl.), which reflects the correlation between individual items and the total score. Low values may result from discrepancies in response coding.

- **Alpha if Item Deleted**, which shows the value of Cronbach's alpha if a given item were removed. This metric helps identify items that do not contribute to internal consistency and could be candidates for elimination.

TABLE IV.
Final evaluation of the OPEX questionnaire items

	Mean if deleted	Var. if deleted	Std Dv.If deleted	Itm-Totl Correl.	Alpha if deleted
How would you rate your current state of health?	5489.92	215.67	14.69	0.11	0.87
How would you rate your current emotional state?	5489.98	208.71	14.45	0.45	0.86
How was your treatment plan determined?	5489.65	215.59	14.68	0.13	0.87
I.1. Did your attending physician communicate your cancer diagnosis to you?	5491.09	217.98	14.76	0.00	0.87
I.2. To what extent did you understand the diagnosis communicated by your physician?	5490.59	209.93	14.49	0.52	0.86
I.3. To what extent did your physician explain your treatment plan?	5490.65	208.49	14.44	0.54	0.86
I.4. To what extent did your physician explain the potential side effects of your treatment?	5490.49	207.73	14.41	0.50	0.86
I.5. Were you informed about the possible course of your illness?	5491.04	215.57	14.68	0.23	0.87
I.6. To what extent did you understand how your illness might progress?	5489.38	204.14	14.29	0.31	0.87
I.7. Did you discuss other aspects of your illness with your physician (e.g., its impact on family, work, etc.)?	5490.69	213.94	14.63	0.26	0.87
I.8. What was the waiting time until a complete diagnosis was established?	5490.36	215.38	14.68	0.06	0.87
I.9. How did you perceive this waiting time?	5490.40	220.39	14.85	-0.11	0.87
I.10. What was the waiting time from diagnosis to the start of treatment?	5490.14	205.13	14.32	0.41	0.86
I.11. How did you perceive this waiting time?	5489.94	204.81	14.31	0.39	0.86
I.12. To what extent was your physician available to listen to your concerns about the illness and treatment?	5490.32	201.76	14.20	0.68	0.86
I.13. How would you evaluate the duration of your consultation?	5490.39	212.99	14.59	0.22	0.87
I.14. Were you satisfied with the amount of time allocated to you?	5490.99	210.53	14.51	0.65	0.86
II.1. How would you assess the behavior of the nurses towards you?	5490.76	204.73	14.31	0.69	0.86

	Mean if deleted	Var. if deleted	Std Dv.If deleted	Itm-Totl Correl.	Alpha if deleted
II.2. How would you assess the way nurses fulfilled their duties (medication administration, IV lines, injections, etc.)?	5490.73	202.05	14.21	0.70	0.86
II.3. During hospitalization, were your complaints regarding discomfort (noise, room temperature, symptoms, side effects, roommates, etc.) addressed?	5490.15	209.21	14.46	0.34	0.86
II.4. Do you believe the nurses treated all patients equally and fairly?	5490.76	207.11	14.39	0.58	0.86
II.5. To what extent do you feel that nurses paid attention to you during treatment?	5490.54	204.85	14.31	0.70	0.86
II.6. Did you discuss about your illness with the nurses?	5490.84	214.85	14.66	0.21	0.87
II.7. Did you discuss other aspects of your illness with the nurses (e.g., impact on family, work, etc.)?	5490.57	213.76	14.62	0.28	0.87
II.8. How would you assess the ability of the nursing team to relate to patients?	5490.66	204.57	14.30	0.68	0.86
III.1. How would you evaluate the quality of information provided about your illness by the medical team (physician, nurses)?	5490.34	201.44	14.19	0.58	0.86
III.2. How would you evaluate the information provided about treatment options?	5490.17	201.56	14.20	0.56	0.86
III.3. How would you evaluate the information regarding potential adverse effects?	5490.02	202.42	14.23	0.53	0.86
III.4. How would you evaluate the information about how your illness might evolve under current treatment?	5490.02	203.89	14.28	0.49	0.86
III.5. How would you evaluate the information about how your illness might evolve under current treatment?	5491.13	217.41	14.74	0.09	0.87
III.6. Were you informed by your physician about methods to relieve discomfort?	5491.07	216.70	14.72	0.14	0.87
III.7. In the past three months, did you discuss the progress of your illness with your physician?	5491.03	215.79	14.69	0.15	0.87
III.8. Were the written documents and other information provided regarding investigations or treatment clear?	5490.75	208.24	14.43	0.34	0.86
III.9. Were you informed about the possibility of undergoing a rehabilitation program (e.g., physiotherapy, lymphatic drainage)?	5489.91	213.87	14.62	0.14	0.87
III.10. Were you informed about the possibility of speaking with a psychologist?	5490.88	216.82	14.72	0.08	0.87
III.11. Were you informed about the possibility of receiving spiritual counseling?	5490.85	218.82	14.79	-0.07	0.87

	Mean if deleted	Var. if deleted	Std Dv.If deleted	Itm-Totl Correl.	Alpha if deleted
III.12. Do you know whether your family physician, rehabilitation center, or home care provider was informed about your treatment upon discharge?	5490.00	224.31	14.98	-0.19	0.88
III.13. Were you informed about the availability of home care services?	5490.63	217.58	14.75	0.01	0.87
IV.1. How would you assess the process of scheduling a consultation at this facility?	5490.32	205.19	14.32	0.59	0.86
IV.2. How would you evaluate the waiting time for scheduling a consultation at this facility?	5491.01	213.15	14.60	0.43	0.86
IV.3. How would you assess the cooperation between physicians within the clinic?	5490.65	204.16	14.29	0.73	0.86
IV.4. Based on your experience at this facility, to what extent would you choose to return?	5490.55	205.69	14.34	0.57	0.86
IV.5. To what extent would you recommend this facility to other patients?	5490.53	199.08	14.11	0.75	0.86
V.1. How often do you feel you received contradictory information about your treatment?	5490.55	211.52	14.54	0.17	0.87
V.2. How often do you feel you received contradictory information about your diagnosis?	5490.70	210.34	14.50	0.23	0.87
V.3. How often do you feel you received contradictory information about your prognosis?	5490.54	210.80	14.52	0.18	0.87
V.4. Do you believe information about your illness was ever withheld from you?	5491.07	217.11	14.73	0.08	0.87
V.5. Once you were informed about treatment options, was your right to choose a specific treatment respected?	5491.06	217.37	14.74	0.06	0.87
V.6. Before treatment or clinical examinations, was your identity verified (e.g., were you asked your name or date of birth)?	5490.94	215.01	14.66	0.15	0.87
VI.1. To what extent do you believe that interactions between your family (caregivers) and the medical team improved your illness experience?	5489.85	224.99	15.00	-0.31	0.88
VI.2. To what extent were your caregivers informed about your diagnosis or treatment options?	5490.19	226.20	15.04	-0.30	0.88
VII.1. How would you evaluate the politeness and courtesy of support staff (receptionists, orderlies, porters)?	5490.69	204.31	14.29	0.73	0.86
VII.2. How would you evaluate the promptness of support staff (receptionists, orderlies, porters)?	5490.65	204.39	14.30	0.74	0.86
VII.3. How would you evaluate the waiting conditions at this facility?	5490.32	203.70	14.27	0.57	0.86
VII.4. To what extent do you believe the waiting times met your expectations?	5490.22	207.28	14.40	0.42	0.86

While not the only statistical procedure employed in such contexts, Cronbach's alpha is by far the most widely recognized indicator of measurement precision, internal consistency, and the reliability of a questionnaire. Typically, the value of Cronbach's alpha tends to increase as the number of items increases.

One of the core aims of item analysis is to identify and either eliminate or revise items that are inappropriate or misaligned with the construct being measured. This process is iterative, involving repeated evaluations of inter-item relationships and item selection based on their contribution to the overall consistency of the scale.

The primary criterion for this process is the value of Cronbach's alpha, which ranges from 0 to 1. For a scale to be considered consistent, the coefficient should approach 1, with 0.70 commonly accepted as the minimum acceptable threshold. In practice, values below 0.60 are generally deemed unacceptable.

Two columns in second table are of particular importance:

- Item-Total Correlation (Itm-Totl Correl.), which reflects the degree of correlation between each item and the total score.
- Alpha if Item Deleted, which shows the expected alpha value if the item were removed from the scale.

The analysis reveals that certain items have very low correlations (<0.3 or in the range of [-0.3 to 0.3]). This suggests that they do not contribute meaningful information regarding the measured construct and may, in fact, introduce noise. First, such items should be examined for coding errors. If correctly coded, the only appropriate solution is to exclude or reformulate them.

As shown in the first table, the final version of the OPEX questionnaire includes 52 items across seven sections, representing an increase of 14 items compared to the initial version.

Following the item-level analysis, 14 new questions were added and several others were reformulated, thereby enhancing both the validity and internal consistency of the OPEX questionnaire as an instrument for evaluating the patient experience in oncology care centers.

The outcome of this process is a robust and psychometrically sound tool, capable of generating reliable and comparable data to support oncology centers in their ongoing efforts to continuously improve the quality of care.

DISCUSSION

A positive patient experience is correlated with overall well-being, which in turn is associated with increased adherence to treatment and improved prognosis. Developing a new instrument to quantify the level of satisfaction among oncology patients is a complex endeavor that requires specialized methods of data processing and analysis. Several methodological approaches were considered to support this process, including content analysis, literature review, the critical incident technique, direct observations, expert judgment, and structured guidance. The present study aimed to construct a psychometrically robust instrument that can be used both in clinical settings and academic research. To ensure the validity of the questionnaire, it is essential to demonstrate that the instrument accurately measures the intended construct and consistently produces reliable results. This process involves establishing content validity through expert evaluation, construct validity through factor analysis and theoret-

ical correlations, and criterion validity by comparing the results with those obtained from established measurement tools.

In the validation of the OPEX questionnaire, two major types of validity were taken into consideration: content validity and construct validity. Content validity refers to the extent to which the items included in a questionnaire are representative of the entire theoretical construct the instrument is designed to measure (13). Content validity should not be assessed until the initial version of the questionnaire has been developed, despite the fact that the construct of interest dictates the items that are written and/or selected during the questionnaire development phase. The process of content validation is a critical component of the development of a new questionnaire, as it guarantees that the instrument accurately represents all pertinent aspects of the theoretical construct it is designed to assess (14).

The content validity of the questionnaire should be assessed by a group of experts who have extensive knowledge in the construct it seeks to measure. These experts evaluate the items' capacity to comprehensively measure the targeted domain and whether they are sufficient and appropriate to adequately capture the construct of interest, acting as a focus group (11). Several approaches are also available to quantify expert assessment of content validity, such as the Content Validity Ratio (CVR) and the Content Validity Index (CVI) form (15). However, because the process of content validation largely depends on how well the expert panel can evaluate the extent to which the construct of interest has been operationalized, the selection of appropriate experts is crucial to ensure that content validity is assessed accurately and meaningfully (16).

Construct validity is the most critical concept in evaluating a questionnaire designed to measure a construct that is not directly observable (e.g., pain, quality of recovery). If a questionnaire lacks construct validity, the results become difficult to interpret, and it is not possible to draw meaningful inferences from the responses to broader behavioral domains. Construct validity can be assessed by examining the associations between the questionnaire and other variables (or measures of a similar construct) with which it is theoretically expected to correlate-positively, negatively, or not at all, depending on the nature of the relationship (17). In practice, the questionnaire of interest is administered to the same groups of individuals as existing instruments that measure similar or different constructs (18).

Given the specific needs of oncology patients, the OPEX questionnaire was developed to assess patient satisfaction across key dimensions of cancer care. Patient interactions were conducted through semi-structured interviews, during which the researcher asked a series of open-ended questions aimed at evaluating various aspects of the patient's experience with oncology healthcare services.

The international literature includes several questionnaires similar to the OPEX instrument developed and validated in this study. These include the EORTC IN-PATSAT32 (19), the Cancer Patient Experiences Questionnaire (CPEQ) (20), and The Consumer Assessment of Healthcare Providers and Systems (CAHPS) Cancer Care Survey (21). However, these tools are not adapted to the specific characteristics of the Romanian healthcare system or the socio-cultural values of the local population.

Thus, a comprehensive validation process-outlined in the previous steps-led to the development of a new questionnaire

specifically designed for oncology patients receiving medical care in Romania. This instrument offers the advantage of capturing the care context and the patient-healthcare provider relationship, with significant implications for the quality of life of oncology patients and the overall improvement of healthcare quality.

CONCLUSIONS

To be effective, a questionnaire must be valid, reliable, clear, concise, and engaging. It should be built on a conceptual framework, with each item assessed for relevance, clarity, and analytical approach. For patients' experiences of patient-centered care, such a tool can capture nuanced operational and human aspects of care, such as staff relationships, organization, safety, and infrastructure. The proposed questionnaire complements quality of life assessments and may offer valuable insights into the care context and patient-staff interactions, with significant implications for the overall well-being of oncology patients. This questionnaire also aims to contribute to the development of an organizational culture in which the patient's voice is heard, analyzed, and translated into concrete actions. Ultimately, we hope that this initiative represents a meaningful step toward a holistic and humanistic approach, in which medical performance is accompanied by compassion, respect, and a deep understanding of the needs of those navigating one of life's most challenging experiences.

DIGITAL *VERSUS* CONVENTIONAL IMPRESSIONS: A COMPARATIVE STUDY IN SINGLE-CROWN FABRICATION (Abstract): **Aim** of the study. This study aimed to assess the dimensional accuracy and time efficiency of digital and conventional impression techniques used in recording complete dental impressions for single-crown fabrication. **Materials and methods:** A standardized typodont model designed for single-crown preparation was used to obtain 45 impressions: 15 with condensation silicone (Zeta Plus with Oranwash), 15 with addition silicone (Elite HD+), and 15 digital impressions using the Primescan AC intraoral scanner. Linear measurements of crown height, cervical widths, and interproximal distances were performed using Dental CAD software. Recording time was documented for each technique. **Results:** Digital impressions exhibited slightly lower mean values at the crown cervical finish line compared with conventional silicones, though all values remained within clinically acceptable limits. Significant differences ($p < 0.001$) were observed for cervical width measurements, while other parameters showed no statistical differences. The digital workflow demonstrated the shortest mean recording time (286 ± 7.39 s), followed by addition silicone (650.8 ± 8.93 s) and condensation silicone (713.67 ± 12.22 s). **Conclusions:** All three impression techniques produced clinically acceptable results. Digital impressions proved to be the most time-efficient and reproducible but tended to slightly underestimate certain dimensions. Although digital systems offer greater efficiency and patient comfort, addition silicone remains the preferred material for many practitioners in cases requiring full-arch or subgingival accuracy. **Keywords:** CONDENSATION SILICONES, ADDITION SILICONES, DIGITAL IMPRESSION.

INTRODUCTION

An impression is defined as a negative replica of the patient's teeth and surrounding tissues, serving as the primary step in the fabrication of indirect restorations such as crowns, bridges, inlays, on lays, orthodontic appliances, and removable prostheses (1-3). To achieve accurate prosthetic design and fabrication, the impression is later converted into a working model using dental stone or other materials. During the laboratory phase, it is converted into a working model (the positive replica) using dental stone or other die materials, allowing for precise prosthetic design and fabrication. Because it plays a crucial role in treatment accuracy, the impression must retain its dimensions, remain stable, and resist distortion. Achieving this requires not only technical skill but also a solid understanding of material science, particularly the behavior

of flow, polymerization, moisture interaction, and tear resistance (4).

Conventional impressions using irreversible hydrocolloids (alginate), polyethers, condensation silicones (polydimethyl siloxanes), and addition silicones (polyvinyl siloxanes) have been the standard in dental practice (5). When properly handled, these materials provide accurate and detailed impressions but are prone to dimensional changes, patient discomfort, and longer processing times due to setting, pouring, and laboratory transfer (6, 7).

The introduction of digital impression systems has revolutionized dental practice. Although the concept appeared in the late 1980s, it became practical only in the early 2000s (8, 9). Early intraoral scanners were oversized, expensive, and limited in performance, but thanks to advancements in optics and software, we now have compact, precise, and user-friendly systems (10). Digital impressions minimize material distortion and operator error, thereby improving precision and patient comfort by eliminating the need for conventional materials (11-13). They also simplify clinical workflows through CAD/CAM integration, allowing faster lab communication and even same-day restorations (14). Despite these benefits, challenges remain, including high equipment costs, the need for training for new users, and difficulties scanning subgingival or edentulous areas (15, 16).

The aim of this study was to evaluate the dimensional accuracy and the recording time of impressions for single-crown fabrication using digital and conventional techniques. To achieve this objective, a null hypothesis was formulated, stating that there are no statistically significant differences between the two methods in terms of dimensional accuracy or the time required to complete an impression.

MATERIALS AND METHODS

The experimental study was conducted at the Faculty of Dentistry, Grigore T. Popa University of Medicine and Pharmacy, Iași. The dental impressions were obtained within the institution's facilities. For the fabrication of the experimental digital models, impressions were taken 15 times from a standardized typodont model designed for single-crown fabrication, using condensation silicone (Zeta Plus with Oranwash, Zhermack SpA, Badia Polesine, Italy) and addition silicone (Elite HD+, Zhermack SpA, Badia Polesine, Italy).

Digital impression. The digital impressions were obtained using a powder-free intraoral scanner, the Primescan AC (Dentsply Sirona, Bensheim, Germany). Prior to scanning, the typodont model was securely positioned and dried to minimize reflective artifacts and ensure optimal surface recognition. The scanning procedure was performed in accordance with the manufacturer’s guidelines, beginning with the occlusal surfaces and then the buccal and oral aspects, to ensure comprehensive data acquisition. Once the full arch scan was completed and verified for precision and completeness, the resulting data were exported in Standard Tessellation Language (STL) format, a widely accepted file type for digital dental workflows and CAD/CAM processing.

For the conventional impression group, digital STL files were generated using a laboratory desktop scanner (Swing DOF, DOF Inc., Seoul, Korea). This device uses a white-light LED source and an L-shaped configuration to capture detailed surface

data, converting the physical impression into a high-resolution digital model.

This protocol enables the generation of digital STL data directly from the impression surface, without the need to pour a conventional gypsum model.

All materials were handled in accordance with the respective manufacturers' instructions, and all impression records were carried out by a single calibrated operator.

Conventional impression. Impressions were obtained using a two-step impression technique using low and high-viscosity silicone materials, a protocol commonly employed in clinical prosthodontics due to its superior ability to capture fine anatomical details with high precision.

To ensure proper retention of the impression materials, medium-sized perforated plastic impression trays (Guangzhou Aurora Health Products Company) were employed. In the first step, an impression was taken using the putty consistency of the selected silicone materials, which were manually loaded into the preselected perforated impression trays. After the putty had set, the light-body silicone material was carefully syringed into the preliminary impression to occupy the negative space corresponding to the dental structures. The tray containing the set putty material was then repositioned onto the typodont model, allowing the low-viscosity material to reproduce fine surface details. The entire assembly was maintained until a complete setting was achieved.

Dimensional accuracy analysis. To evaluate the dimensional accuracy of the impressions, digital linear measurements were performed using Dental CAD 3.0 Galway (exocad GmbH, Darmstadt, Germany) (17). The following parameters were assessed:

- crown height of the maxillary second premolar (tooth 2.5) and first molar (tooth 2.7);
- buccal, distal, oral, and mesial measurements at the cervical preparation of the abutment first molar (tooth 2.6);
- mesio-distal and buccal-palatal dimensions of 2.6 abutment measured at the occlusal level;
- mesial and distal distance between the contact points (fig. 1).

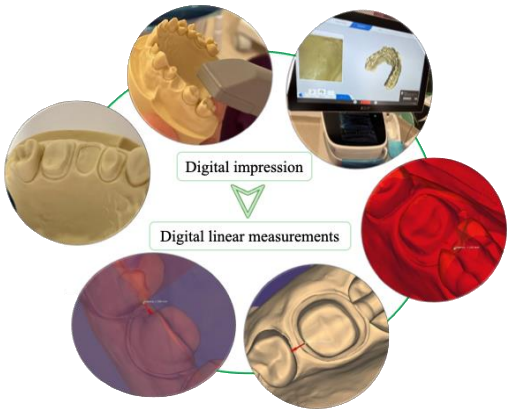

Fig. 1. Schematic representation of the digital impression and linear measurement workflow.

Time efficiency analysis. For the conventional impression procedures, recording time was measured in seconds, from the selection of an appropriately sized impression tray to the removal of the fully set material from the typodont model. Similarly, for the digital impression workflow, the recording time was documented in seconds to allow for direct comparison with the conventional method. In this case, timing began at the moment the intraoral scanner tip was first positioned on the model and concluded upon the completion of the full-arch scan, as indicated by the scanner's software.

Statistical analysis. Statistical analysis was carried out using SPSS software, version 26.0 (SPSS Inc., Chicago, IL, USA). The data were first evaluated for normality using the Kolmogorov-Smirnov and Shapiro-Wilk tests, and descriptive statistics were then applied. For comparisons between groups involving digital measurements obtained from digital models, one-way ANOVA and Kruskal-Wallis tests were used. A significance level of $p < 0.05$ was considered statistically relevant throughout the evaluation.

RESULTS

Dimensional accuracy. A total of 45 samples were analyzed to assess the dimensional accuracy of the three impression techniques, using condensation silicone, addition silicone, and an intraoral scanner. The comparative analysis of the measured landmarks revealed consistent dimensional stability across all parameters, with minor variations among the techniques (tab. I). Normality tests (Kolmogorov-Smirnov and Shapiro-Wilk) indicated no significant deviation from a normal distribution for eight parameters ($p > 0.05$).

TABLE I.

Measured parameters (N=45).

Parameters	Mean ± SD	Min.	Max.	Kolmogorov-Smirnov Sig.	Shapiro-Wilk Sig.
2.5 Crown height	7.530 ± 0.095	7.346	7.733	0.054	0.053
2.7 Crown height	5.844 ± 0.094	5.675	6.022	0.200	0.093
2.6 Mesio-distal dimension	6.882 ± 0.095	6.694	7.088	0.036	0.194
2.6 Buccal-palatal dimension	6.654 ± 0.093	6.471	6.822	0.054	0.033
Mesial contact distance	2.272 ± 0.036	2.201	2.339	0.060	0.054
Distal contact distance	2.026 ± 0.036	1.966	2.104	0.084	0.093
Mesial cervical width	0.885 ± 0.011	0.850	0.910	0.160	0.351
Distal cervical width	0.998 ± 0.020	0.956	1.043	0.200	0.400
Buccal cervical width	0.992 ± 0.023	0.949	1.042	0.200	0.187
Palatal cervical width	1.050 ± 0.027	1.003	1.111	0.039	0.027

SD - standard deviation; Min.- Minimum value; Max.- Maximum value; significant level $p < 0.05$

Material-based comparisons revealed uniform dimensional behavior among the three evaluated impression techniques. Across most parameters, condensation silicone pro-

duced slightly higher mean values, while digital impressions yielded marginally lower values. Differences in crown height, mesio-distal, buccal-palatal, and contact distances were not statistically significant ($p > 0.05$), indicating comparable trueness among the materials for these parameters. In contrast, statistically significant differences ($p < 0.005$) were observed in cervical width measurements, with condensation silicone showing higher mean values than addition silicone and digital techniques (tab. II).

TABLE II.

Dimensional measurements among the study's impression groups.

Parameters	Intraoral scanner	Condensation silicone	Addition silicone
	Mean ± SD	Mean ± SD	Mean ± SD
2.5 Crown height	7.560± 0.096	7.543 ± 0.101	7.488± 0.076
	one-way ANOVA, p = 0.093		
2.7 Crown height	5.817± 0.089	5.855 ± 0.096	5.859 ± 0.098
	one-way ANOVA, p = 0.419		
2.6 Mesio-distal dimension	6.905 ± 0.105	6.883 ± 0.106	6.856 ± 0.0681
	one-way ANOVA, p = 0.381		
2.6 Buccal-palatal dimension	6.647 ± 0.074	6.651 ± 0.090	6.664 ± 0.115
	Kruskal-Wallis Test, p = 0.789		
Mesial contact distance	2.265 ± 0.038	2.282 ± 0.031	2.270 ± 0.038
	one-way ANOVA, p = 0.416		
Distal contact distance	2.040 ± 0.037	2.013 ± 0.034	2.025 ± 0.034
	one-way ANOVA, p = 0.143		
Mesial cervical width	0.877 ± 0.012	0.887 ± 0.009	0.890 ± 0.008
	one-way ANOVA, p = 0.005		
Distal cervical width	0.985 ± 0.016	1.016 ± 0.016	0.993 ± 0.015
	one-way ANOVA, p < 0.001		
Buccal cervical width	0.974 ± 0.011	1.019 ± 0.012	0.983 ± 0.012
	one-way ANOVA, p < 0.001		
Palatal cervical width	1.032 ± 0.015	1.082 ± 0.016	1.034 ± 0.012
	Kruskal-Wallis Test, p < 0.001		

SD - standard deviation; Min.- Minimum value; Max.- Maximum value; significant level $p < 0.05$

Impression recording time. The mean impression recording times differed significantly across the three impression techniques (tab. III and fig 2). The digital impression group recorded the shortest average time (286 ± 7.36 seconds), followed by the addition silicone group (650.80 ± 8.93 seconds), while the condensation silicone group required the longest time (713.67 ± 12.22 seconds).

TABLE III.
Recording time among the study's impression groups.

Impression Recording Time (s)					
Material Type	**N**	**Mean ± SD**	**Min.**	**Max.**	**Kruskal-Wallis Test**
Intraoral scanner (Primescan AC)	15	286.00 ± 7.39	275	299	p < 0.001
Condensation silicone (Zeta Plus + Oranwash, Zhermack SpA)	15	713.67 ± 12.22	694	737	
Addition silicone (Elite HD+, Zhermack SpA)	15	650.80 ± 8.93	637	670	

SD - standard deviation; Min.- Minimum value; Max.- Maximum value; significant level $p < 0.05$

DISCUSSION

Proper marginal adaptation is vital for maintaining oral health and ensuring the longevity and structural integrity of tooth-supported fixed prostheses. Accurate margins reduce the risk of restoration fractures, retention loss, postoperative sensitivity, periodontal issues, and recurrent caries. In contrast, poor adaptation facilitates bacterial microleakage and cement dissolution, encouraging secondary caries and plaque-induced periodontal disease (18-22).

Several factors influence marginal fit, including the finish line design, spacer application, cementation protocol, and the type of restorative material used (23-25). According to McLean and von Fraunhofer, a marginal gap of up to 0.12 mm is generally acceptable. Achieving an accurate intraoral impression is essential for producing precisely fitted fixed dental prostheses (26). Conventional techniques can provide reliable results when performed correctly, but they require technical proficiency and careful handling of impression materials to avoid errors such as marginal distortion,

voids, and tissue displacement.

The results of this study showed that digital impressions exhibited slightly lower mean values at the crown cervical finish line. Although these values remained within clinically acceptable limits, they were significantly different from those obtained with conventional condensation silicone impressions. No other statistically significant differences were found between the measurements obtained from digital models generated by intraoral scanning and those derived from conventional silicone impressions. These findings are consistent with the research by Ender *et al*. (27, 28). In their earlier study, the authors compared several conventional impression materials, including polyether (POE), vinylsiloxanether (VSE), and alginate (ALG), along with four digital intraoral scanners (CEREC Bluecam (CER), CEREC Omnicam (OC), Cadent iTero (ITE), and Lava COS (LAV)) using a reference model with a known morphology. The results indicated that VSE and CER achieved the highest trueness and precision across the full dental arch, while POE and ALG exhibited greater deviations. The authors concluded that conventional and digital impression techniques differ in full-arch accuracy, with digital systems showing higher local deviations along the arch (27). One year later, the same authors reported that digital quadrant impressions demonstrated precision comparable to that of conventional methods, though differences persisted in absolute values and deviation patterns (28).

Many studies have evaluated the marginal fit of restorations fabricated using different impression and manufacturing techniques. In the study conducted by Seelbach *et al*. (29), twenty putty-wash impressions (ten single-step and ten two-step) were taken from the same model using a polyvinyl siloxane (PVS) impression material and compared with thirty digital impressions recorded using three different intraoral scanners. The authors reported satisfactory adaptation in restorations fabricated with CEREC Bluecam, Lava COS, iTero, and 3Shape TRIOS scanners, with an accuracy comparable to that of conventional impression techniques.

An S *et al*. (30) found that the iTero system provided marginal accuracy comparable to that of milled polyurethane models. Pedroche *et al*. (31) also observed that intraoral scans yielded better marginal precision than extraoral scans of PVS impressions. Other authors (32-36) confirmed that direct digital impressions often achieve equal or superior fit compared with indirect methods, though results vary by scanner type. In contrast, Shembesh *et al*. (37) reported mixed outcomes, with poorer fit for iTero and improved results for the 3M True Definition Scanner.

In the present research, the digital workflow showed the shortest recording time, 286 ± 7.36 s, compared with 650.80 ± 8.93 s for addition silicones and 713.67 ± 12.22 s for condensation silicones. Similar conclusions were drawn by Yuzbasioglu *et al*. (38), who reported that digital impressions reduced both total treatment and impression times, with average durations of 248.48 ± 23.48 s for digital versus 605.38 ± 23.66 s for conventional impressions. This trend was similarly observed in other in vivo studies, in which total procedure times and impression-specific durations consistently favored digital techniques. The efficiency of intraoral scanning systems likely stems from eliminating the steps required

in traditional methods, such as material mixing, tray insertion, setting time, and removal. Moreover, real-time visualization and immediate error correction reduce the need for retakes, which is not always feasible with conventional materials (32,39).

Based on the findings of this study, the null hypothesis stating that all impression techniques are equally precise and time-efficient must be rejected.

Beyond dimensional accuracy and time efficiency, digital impressions offer additional clinical advantages, including improved patient comfort by avoiding bulky trays and unpleasant materials, particularly beneficial for patients with a gag reflex or anxiety. However, certain limitations remain. Challenges such as the high initial cost of intraoral scanners, the need for training, and occasional difficulty in capturing subgingival margins and reflective surfaces continue to pose barriers to universal adoption.

The *In Vitro* nature of the present study limits its direct clinical applicability, as it does not account for the complex in vivo factors that can influence impression accuracy, including saliva, blood, patient or operator movement, limited access, and soft tissue variability. The use of point-based measurements rather than automated analytical software and the small sample size further constrains the generalizability of the results. Consequently, future in vivo studies employing diverse intraoral scanners are needed to validate the accuracy and reliability of digital and conventional impression systems under real clinical conditions.

CONCLUSIONS

Within the limitations of this *in Vitro* study, the analysis revealed the following findings:

- condensation silicone showed slightly higher mean values than addition silicone and digital impressions.

- digital impressions demonstrated excellent reproducibility, speed, and ease of use but tended to slightly underestimate certain dimensions compared with conventional elastomeric materials;

- all three impression techniques provided measurements within clinically acceptable limits, confirming their suitability for prosthodontic use.

Digital systems represent a reliable alternative for single-unit and quadrant restorations; however, for full-arch impressions or recordings of subgingival margins, conventional addition silicones are still recommended.

ANTI-INFLAMMATORY EFFICACY OF NSAIDS AND THEIR COMBINATIONS WITH ANTIBIOTICS IN A RAT MODEL OF ACUTE CARRAGEENAN-INDUCED INFLAMMATION (Abstract): Acute inflammation is a fundamental pathophysiological process involved in numerous diseases. The carrageenan-induced paw edema model in rodents is a well-established method for evaluating anti-inflammatory agents. Nonsteroidal anti-inflammatory drugs (NSAIDs), such as diclofenac (DCF) and ketoprofen (KET), exert their effects primarily through cyclooxygenase inhibition, while certain antibiotics, including cefuroxime (CFX) and levofloxacin (LFC), may indirectly influence inflammatory pathways. This study assessed the anti-inflammatory effects of DCF and KET, administered alone or combined with CFX or LFC, in rats with carrageenan-induced paw edema. **Materials and methods**: Forty-five Wistar rats were divided into nine groups (n = 5) receiving saline, NSAIDs, antibiotics, or their combinations. Treatments were given intraperitoneally every 12 hours for three days. Acute inflammation was induced by subcutaneous injection of 1% carrageenan into the right hind paw. Paw volume was measured at baseline and at 6, 24, and 72 hours. Edema was expressed as percentage increase in paw volume, and anti-inflammatory activity as percentage of edema inhibition. Statistical analysis was performed using ANOVA method. **Results**: Edema peaked at 6 hours after carrageenan injection. Both NSAIDs significantly reduced paw swelling at all time points, with DCF showing greater and more sustained efficacy than KET. Antibiotics alone had minimal impact, except for a modest reduction with CFX at 24 hours. Combination therapies maintained or slightly enhanced anti-inflammatory effects, particularly KET combined with CFX. **Conclusions:** NSAIDs were the main contributors to the anti-inflammatory response, with DCF demonstrating superior potency. Although antibiotics showed limited direct effects, certain combinations may enhance therapeutic outcomes in acute inflammation. **Keywords:** ACUTE INFLAMMATION, PAW EDEMA, CARRAGEENAN, DICLOFENAC, KETOPROFEN, CEFUROXIME, LEVO-FLOXACIN, RATS.

INTRODUCTION

Acute inflammation is a complex physiological response to tissue injury or chemical irritants, characterized by edema, redness, pain, and increased vascular permeability. It is a critical protective mechanism,

yet uncontrolled or excessive inflammation underlies numerous pathological conditions, including autoimmune diseases, chronic pain, and cardiovascular disorders. Experimental models that reliably reproduce acute inflammation are essential for understanding the underlying mechanisms and evaluating potential anti-inflammatory therapies. Among these, the carrageenan-induced paw edema in rodents is a widely used and well-standardized model, reproducing key features of human acute inflammation, including the exudative phase and the subsequent resolution (1, 2).

NSAIDs act primarily through inhibition of COX enzymes (3), thereby reducing prostaglandin synthesis, which in turn decreases vasodilation, vascular permeability, and pain associated with acute inflammation (4, 5). DCF is widely recognized for its strong and preferential inhibition of the COX-2 enzyme, a key isoform responsible for the synthesis of pro-inflammatory prostaglandins during tissue injury and inflammation. By selectively suppressing COX-2 activity, DCF effectively decreases the production of prostaglandins such as PGE_2, which are directly involved in mediating pain, swelling, and fever (3). This mechanism underlies DCF's ability to produce a rapid onset of analgesic action and a sustained anti-inflammatory response, making it highly effective in both acute and chronic inflammatory disorders, including osteoarthritis, rheumatoid arthritis, and postoperative pain management. Its pharmacological profile is characterized by potent peripheral and central analgesic properties, which contribute to its strong clinical efficacy (6). Moreover, its relatively higher COX-2 selectivity compared to other NSAIDs contributes to a more favorable gastrointestinal safety profile, although risks of hepatotoxicity and cardiovascular effects remain considerations with long-term use (5, 6). In contrast, KET exhibits a more balanced inhibitory action on both COX-1 and COX-2 enzymes, leading to a broader but slightly less selective suppression of prostaglandin synthesis. This dual inhibition contributes to effective reduction of inflammatory edema, pain, and tissue swelling through decreased vascular permeability and modulation of inflammatory mediators. However, because COX-1 plays a role in maintaining gastric mucosal protection and platelet function, KET's balanced inhibition is associated with a slightly increased risk of gastrointestinal irritation and bleeding compared with more COX-2–selective agents like diclofenac (7). Despite its somewhat lower anti-inflammatory potency relative to DCF, KET remains an effective therapeutic option, particularly in conditions where edema reduction and modulation of both central and peripheral inflammatory pathways are desired. Its balanced COX inhibition profile also provides reliable efficacy across a wide range of inflammatory and musculoskeletal disorders, making it a versatile NSAID for pain and inflammation control (8).

CFX and LFC are both broad-spectrum antibacterial agents commonly used in the treatment of a wide range of bacterial infections, but they belong to different pharmacological classes and act through distinct mechanisms. CFX is a second-generation cephalosporin antibiotic that exerts its bactericidal effect by inhibiting bacterial cell wall synthesis. It binds to penicillin-binding proteins located inside the bacterial cell wall, interfering with the final transpeptidation step of peptidoglycan synthesis, which is essential for maintaining cell wall structural integrity (9). As a

result, CFX causes cell lysis and bacterial death. It is particularly suited for infections caused by susceptible Gram-positive cocci and β-lactamase-producing Gram-negative bacilli, being used in respiratory tract infections, skin and soft tissue infections, urinary tract infections, and infections of the ear, nose, and throat. Pharmacokinetically, CFX demonstrates good tissue penetration and is primarily excreted unchanged via the kidneys, making dose adjustment necessary in patients with renal impairment (9).

LFC is a fluoroquinolone antibiotic and the L-isomer of ofloxacin, with potent bactericidal activity mediated by inhibition of bacterial DNA gyrase and topoisomerase IV, two enzymes crucial for bacterial DNA replication, transcription, repair, and recombination. This dual inhibition results in rapid bacterial cell death and prevents the development of resistance mechanisms (10). LFC exhibits broad-spectrum activity against Gram-positive, Gram-negative, and atypical pathogens, making it highly effective in the treatment of community-acquired pneumonia, sinusitis, bronchitis, urinary tract infections, prostatitis, and skin infections. It is primarily eliminated renally and requires dose adjustment in renal dysfunction. However, caution is advised due to potential adverse effects such as tendinopathy, QT interval prolongation, central nervous system effects, and, rarely, dysglycemia (10).

In addition to classical NSAIDs, selected antibiotics such as CEF and LFC have been reported to influence inflammatory pathways indirectly, potentially modulating cytokine release or oxidative stress, though their anti-inflammatory effects are generally secondary to their antimicrobial action (8, 9). Studying these agents alone and in combination with NSAIDs may reveal pharmacological interactions that enhance or modify the anti-inflammatory response.

This study **aimed** to evaluate the dynamics of carrageenan-induced paw edema in Wistar rats and to compare the anti-inflammatory efficacy of DCF and KET, alone and in combination with CFX or LFC. The pharmacological rationale was to investigate how well-characterized NSAIDs exert their effects in this model, and whether co-administration with antibiotics could influence the inflammatory response, providing insight into potential synergistic or modulatory interactions relevant for therapeutic strategies.

Animals. White Wistar rats (200-250 g) from the bio base of Grigore T. Popa University of Medicine and Pharmacy, Iași, were used for the experiments. Animals were acclimated for one week under standard laboratory conditions (temperature 21 ± 2 °C, relative humidity 50–70%, 12-hour light/dark cycle) and tested between 8:00-12:00 a.m. to avoid chronobiological influences. During acclimation, rats received standardized pellet feed and monitored water ad libitum. On the day of the experiment, food and water were withheld.

Protocol of the research

The researches were conducted under controlled laboratory conditions at the CEMEX - Advanced Research and Ostin C. Mungiu Development Center for Experimental Medicine of the Grigore T. Popa University of Medicine and Pharmacy from Iași, ensuring standardized environmental parameters and animal care throughout the study.

For the experiment, nine groups of five animals each were used, receiving intraperitoneal administrations every 12 hours for three days at the same volume as follows: Group 1 (coded C): saline solution; Group

2 (KET): ketoprofen 15 mg/kg; Group 3 (DCF): diclofenac 15 mg/kg; Group 4 (CFX): cefuroxime 20 mg/kg; Group 5 (LFC): levofloxacin 5 mg/kg; Group 6 (KET+CFX): ketoprofen 15 mg/kg + cefuroxime 20 mg/kg; Group 7 (KET+LFC): ketoprofen 15 mg/kg + levofloxacin 5 mg/kg; Group 8 (DCF+CFX): diclofenac 15 mg/kg + cefuroxime 20 mg/kg; Group 9 (DCF+LFC): diclofenac 15 mg/kg + levofloxacin 5 mg/kg.

The carrageenan-induced hind paw inflammation model in rats is recognized as one of the most widely used and well-standardized experimental methods for studying acute inflammation (1, 2, 11), providing valuable insights into inflammatory mechanisms and serving as an effective tool for evaluating substances with potential anti-inflammatory activity. Before administering the irritant, animals were locally anesthetized with 20% benzocaine spray to minimize discomfort. Subsequently, 0.1 mL of 1% carrageenan solution (w/v in saline solution) was injected subcutaneously into the plantar surface of the right hind paw using a fine 27G needle. Paw volume measurements were used as objective indicators of edema, complemented by clinical observation of redness, swelling, and pain-related behaviors. Paw volume was assessed with a plethysmometer (Ugo Basile) to establish baseline values and then at 6, 24, and 72 hours post-inflammation induction. Volume increase was considered an objective indicator of edema intensity. Animals were also directly observed for clinical signs such as redness, local swelling, pain, and behavioral changes. Edema intensity was expressed as a percentage of relative extinction of paw edema from baseline (%EPE), calculated using the following formula (12): %EPE = [(Ve – Vb) / Vb] × 100, where Ve is the paw volume at the time of evaluation and Vb is the initial paw volume (at baseline).

Anti-inflammatory activity was evaluated by measuring the ability to reduce inflammatory paw edema and was expressed as the percentage of edema inhibition (%EI), calculated using the following formula: %EI = [(%EPEc − %EPEt) / %EPEc] × 100, where % EPEc represents the percentage increase in paw volume in the control group, and %EPEt represents the percentage increase in paw volume in the treated group. In this acute inflammation model, a significant reduction in paw volume compared to the control group was interpreted as evidence of an anti-inflammatory effect of the tested substance (13).

Ethical aspects. Our experimental research was conducted in full compliance with both national and international ethical standards governing the use of animals for scientific purposes. The experimental research protocol was reviewed and approved by the Ethics and Scientific Research Committee of the Grigore T. Popa University of Medicine and Pharmacy Iași, receiving a favorable opinion as documented by Certificate No. 553/06.03.2025 and Project Authorization No. 79/15.04.2025. All procedures strictly adhered to the principles outlined in European Directive 2010/63/EU (14) and the Romanian Law No. 43/2014 (15) concerning the protection of animals used for scientific purposes.

Statistical analysis. Experimental data were analyzed using SPSS variant 24 for Windows. Group comparisons were performed mainly with one-way ANOVA, followed by Tukey's post-hoc test when significant differences were found. Data were expressed as means ± standard deviation, with variance and interquartile range calculated.

Independent two-group comparisons used t-tests or, if assumptions were unmet, the non-parametric Kruskal–Wallis test. Pearson and Spearman coefficients assessed linear and rank correlations, respectively. Simple and multiple linear regression evaluated the influence of one or more independent variables on a dependent variable. Statistical significance was set at $p < 0.05$.

RESULTS

The intraplantar injection of 1% carrageenan in C animals induced acute local inflammation, shown by increased paw volume, redness, and paw-licking behavior. Baseline paw volume values were similar across groups ($p>0.05$), ensuring comparability and serving as a reference for %EPE and %EI calculations.

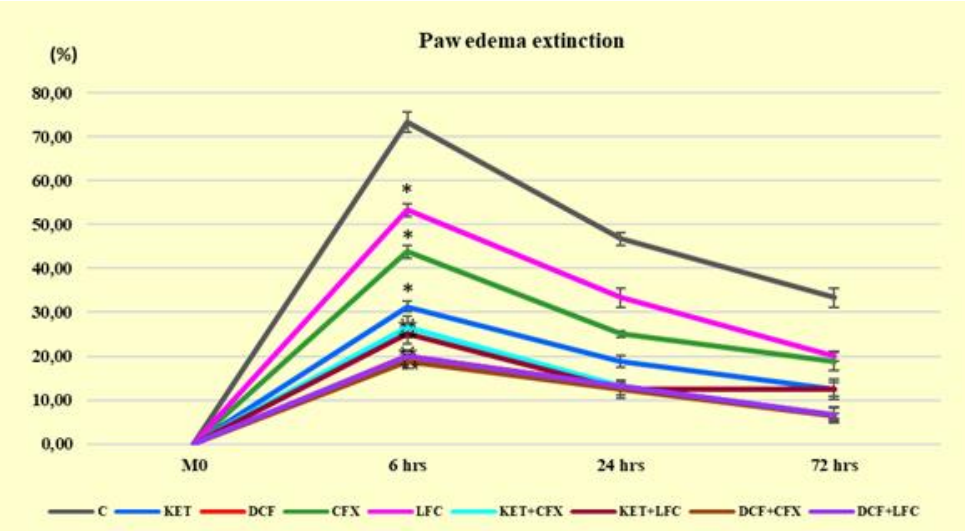

Fig. 1. The paw inflammation test - %EPE.
Each value represents the average ± S.D. (n = 5). *p<0.05, **p<0.01 *vs.* C group.

Six hours after injection, the C group exhibited a marked paw volume increase (0.26±0.04 vs. baseline 0.15±0.01), confirming edema. DCF significantly reduced edema (**p<0.01; 0.18±0.01), indicating effective prostaglandin inhibition. KET *al*so reduced edema (*p<0.05; 0.21±0.01), but less than DCF. CFX and LFC alone had no significant effect (0.23±0.02 and 0.23±0.01). Combinations DCF+CFX and DCF+LFC produced a significant edema reduction (**p<0.01; 0.19±0.01 and 0.18±0.02), similar to DCF alone, showing antibiotics did not impair anti-inflammatory activity. KET+CFX (0.19±0.01) and KET+LFC (0.20±0.01) also reduced edema (*p<0.05), though less than DCF combinations (fig. 1).

At 24 hours post-inflammation, edema in the C group remained elevated but slightly decreased from 6 hours, indicating the start of natural resolution. NSAID-treated groups showed markedly lower edema. DCF significantly reduced paw volume (**p<0.01; 0.17±0.02 vs. 0.22±0.02 in C), confirming its efficacy in the intermediate phase. KET *al*so reduced edema (*p<0.05; 0.19±0.03), though less than DCF (fig. 1). CFX alone caused a modest but significant reduction (*p<0.05; 0.20±0.01), while LFC showed a non-

significant decrease. Combinations KET+CFX and DCF+LFC produced significant edema reduction (**p<0.01; 0.17±0.01), with CFX enhancing KET's effect, while LFC did not influence DCF. KET+LFC (0.18±0.02) and DCF+CFX (0.18±0.01) also significantly reduced edema (*p<0.05), suggesting additional potentiation compared to NSAID monotherapy (fig. 1).

At 72 hours post-carrageenan, edema in the C group decreased compared to 6 and 24 hours but remained above baseline, indicating partial persistence of inflammation. NSAID-treated groups, maintained edema reduction. DCF significantly reduced edema (**p<0.01; 0.18±0.02 vs. 0.20±0.01 in C), showing long-lasting anti-inflammatory efficacy. KET *al*so reduced edema (*p<0.05; 0.18±0.02), though less than DCF (fig. 1).

CFX and LFC alone had no significant effect (0.19±0.01 and 0.19±0.02). Combinations KET+CFX and DCF+LFC significantly decreased edema (**p<0.01; 0.16±0.01), with CFX enhancing KET's effect, while LFC did not clearly affect DCF. DCF+CFX also caused a substantial reduction (**p<0.01; 0.17±0.01), whereas KET+LFC showed a decrease (0.18±0.02) without statistical significance (fig. 1).

The analysis of %CE showed the time course of inflammation at 6, 24, and 72 hours. In the C group, %CE peaked at 6 hours, indicating the acute phase, partially decreased at 24 hours, and further declined by 72 hours, though remaining above baseline.

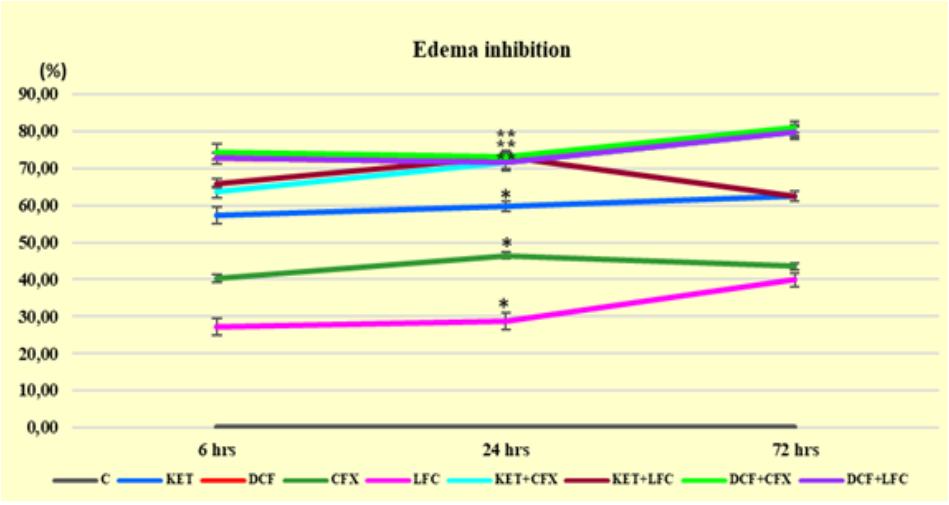

Fig. 2. The paw inflammation test - %EI.
Each value represents the average ± S.D. (n = 5). *p<0.05, **p<0.01 *vs.* C group.

NSAID-treated groups showed significant %CE reductions. KET caused the strongest decrease (**p<0.01 at 6 hours) and maintained significant inhibition at 24 and 72 hours, demonstrating sustained anti-inflammatory activity. DCF also reduced %CE (*p<0.05 at 6 and 24 hours), but less than KET, with a smaller effect at 72 hours.

CFX and LFC alone did not significantly alter %CE, confirming no inherent anti-inflammatory effect. NSAID-antibiotic combinations mirrored NSAID effects:

KET+CFX and KET+LFC matched KET *al*one, while DCF+CFX and DCF+LFC were similar to DCF monotherapy. Overall, KET showed the strongest anti-inflammatory profile, DCF a moderate effect, and antibiotics alone had no impact.

The determination of the %EI allowed a comparative assessment of the anti-inflammatory efficiency of the tested substances relative to C group. The %EI graph provides a direct visualization of the effectiveness of the tested treatments. NSAIDs exhibited the highest inhibition values, with a consistent effect throughout the 72-hour period. DCF stood out through its superior, rapidly established, and sustained inhibition, confirming its strong anti-inflammatory potency. KET *al*so produced a significant inhibitory effect, though slightly lower compared to DCF (fig. 2). Antibiotics administered alone showed low %EI values, close to those of C group, with only a slight influence observed for CFX at 24 hours, suggesting that these substances do not exert a relevant anti-inflammatory effect in this model. The combinations demonstrated inhibition comparable to that achieved with NSAIDs alone, indicating that antibiotics do not diminish anti-inflammatory efficacy (fig. 2). In the case of the KET+CFX combination, an amplification of the inhibitory effect was observed, whereas other associations had a less evident impact. In conclusion, the %EI confirms the major role of NSAIDs, particularly DCF, in limiting inflammation and suggests that some combinations, especially KET+CFX, may enhance the anti-inflammatory response.

DISCUSSION

The present study investigated the temporal profile of carrageenan-induced paw edema in Wistar rats and compared the anti-inflammatory effects of the NSAIDs, KET, and DCF, administered alone or in combination with two antibiotics of distinct pharmacological classes: the fluoroquinolone LFC, and, and the cephalosporin, CFX.

The carrageenan model produced the expected biphasic inflammatory response, an initial exudative phase followed by a proliferative cellular phase, confirming its reliability as a standard model for evaluating anti-inflammatory agents. The inflammation developed progressively, reaching its maximum intensity 6 hours after administration of the chemical irritant, after which it began to gradually subside, though still persisting at 72 hours of the experiment. These results are consistent with data reported in the literature regarding the evolution of carrageenan-induced paw edema in rats (16, 17).

Quantitative paw volume measurements, complemented by clinical observations such as redness, swelling, and pain, enabled a comprehensive assessment of the inflammatory response. Carrageenan administration elicited rapid edema formation, peaking between 3 and 6 hours and progressively declining over 72 hours, in agreement with the classic pattern described in the literature (18, 19). Both NSAIDs significantly reduced paw edema, confirming their capacity to suppress acute inflammation via COX inhibition and the consequent reduction in prostaglandin synthesis (4, 20). DCF demonstrated greater potency and a more sustained anti-inflammatory effect than KET, in line with previous evidence highlighting its higher COX-2 selectivity and prolonged pharmacodynamic action (21).

LFC showed a modest anti-inflammatory influence, particularly during the later stages of the inflammatory process (24-72 hours). This finding supports reports that fluoroquinolones possess secondary immunomodulatory actions independent of their antimicrobial properties. Prior studies have

demonstrated that LFC can downregulate the production of pro-inflammatory cytokines such as TNF-α and IL-6, modulate nitric oxide synthesis, and reduce neutrophil activity (22). These mechanisms may explain the delayed yet perceptible reduction in edema observed in the present study, suggesting that LFC could indirectly contribute to inflammatory resolution through modulation of immune mediators. In contrast, CFX exerted minimal influence on the inflammatory process, consistent with the general pharmacological characteristics of β-lactam antibiotics, which act primarily through inhibition of bacterial cell wall synthesis and lack direct anti-inflammatory or immunomodulatory effects. Importantly, CFX did not interfere with the anti-inflammatory activity of the NSAIDs, indicating pharmacological compatibility and safety in combined administration.

When NSAIDs were administered together with the antibiotics, the overall anti-inflammatory efficacy was maintained or slightly enhanced, suggesting potential additive or complementary effects. The observed trends may reflect the combined modulation of distinct inflammatory pathways, with NSAIDs acting primarily through prostaglandin suppression and fluoroquinolones exerting secondary effects on cytokine and oxidative stress regulation.

Overall, these findings reaffirm the potent and sustained anti-inflammatory efficacy of classical NSAIDs and highlight the potential modulatory role of fluoroquinolones such as LFC in the inflammatory process. CFX did not display intrinsic anti-inflammatory properties but was pharmacologically compatible with NSAID therapy. Collectively, the results support further research into the molecular mechanisms underlying the interactions between anti-inflammatory agents and antimicrobial drugs, particularly in pathological conditions involving both infection and inflammation.

Combination therapy with NSAIDs and antibiotics resulted in variable but generally additive or synergistic anti-inflammatory effects. The enhanced efficacy observed in treatments such as KET+CFX and DCF+LFC may arise from complementary mechanisms, NSAIDs mitigating prostaglandin-mediated vasodilation and nociception, while certain antibiotics modulate cytokine expression or oxidative pathways (22). Notably, antibiotic co-administration did not compromise NSAID efficacy, underscoring their potential compatibility and therapeutic advantage in managing conditions that involve both infection and inflammation. These outcomes are consistent with previous experimental findings demonstrating improved anti-inflammatory responses when fluoroquinolones are combined with NSAIDs (23).

The consistent superiority of DCF over KET throughout the experimental period aligns with pharmacodynamic evidence that DCF achieves higher tissue penetration and sustains COX inhibition for a longer duration (6, 24). Furthermore, the persistence of NSAID activity over 72 hours reinforces the reliability of the carrageenan model in discriminating between drug potency and duration of action.

These results reinforce existing evidence of the robust anti-inflammatory properties of classical NSAIDs while revealing that certain antibiotics, particularly CFX, may exert modulatory effects capable of enhancing or prolonging NSAID-mediated responses. This observation supports growing evidence that fluoroquinolones can influence host inflammatory pathways and highlights the need for further investigation into their potential role as adjuncts in the management of

inflammatory conditions (25).

By integrating the quantitative and qualitative assessments, this research provides a comprehensive evaluation of both classical anti-inflammatory agents and the potential modulatory effects of antibiotics, highlighting the translational significance of these findings for the development of more effective and targeted therapeutic strategies for managing acute inflammation. The results have the potential to inform future clinical applications, optimize drug combinations, and advance our understanding of multimodal approaches to controlling inflammatory responses.

The carrageenan-induced inflammation model proved reliable for studying acute inflammation. NSAIDs, especially DCF, demonstrated consistent and strong anti-inflammatory effects, while antibiotics, particularly CFX, showed possible modulatory influence when combined with NSAIDs. These findings highlight that antibiotics may enhance or modify NSAID-mediated anti-inflammatory responses, opening perspectives for further investigation into their combined therapeutic potential.

CONCLUSIONS

Our research showed that the tested NSAIDs significantly reduced edema throughout the experimental period, with DCF demonstrating greater and more sustained efficacy than KET. Antibiotics alone had minimal impact on inflammation, except for a slight late reduction observed with CFX at 24 hours. DCF maintained consistent anti-inflammatory activity when combined with antibiotics, reflecting a stable pharmacodynamic profile. In contrast, KET showed enhanced efficacy when associated with CFX, while its combination with LFC offered no additional benefit.

Overall, anti-inflammatory effects in the carrageenan-induced model were mainly driven by NSAIDs, with DCF serving as the reference for potency and persistence. Although antibiotics did not exhibit direct anti-inflammatory action, certain combinations, particularly KET with CFX, appeared to optimize therapeutic outcomes, supporting the potential value of multi-drug strategies for improved inflammation management.

IN VIVO BIOCOMPATIBILITY EVALUATION OF NORFLOXACIN-LOADED CHITOSAN NANOFIBERS AND BORONIC ALDEHYDE-FUNCTIONALIZED DERIVATIVES IN RAT (Abstract): Chitosan-based nanofibers can serve as carriers for antimicrobial agents, providing controlled drug release and biocompatibility, which are crucial for tissue integration and healing. This study **aimed** to evaluate the *in vivo* biocompatibility of norfloxacin-loaded chitosan nanofibers (NorC) and norfloxacin-loaded chitosan nanofibers functionalized with boronic aldehyde (NorCB), in comparison with standard wound treatments in rats. **Materials and methods:** NorC fibers were prepared via electrospinning of chitosan (CHIT) solution containing norfloxacin (Nor). NorCB fibers were obtained by imination of NorC fibers with boronic aldehyde. The study included four groups of Wistar rats: (i) a negative control group, which remained intact with no procedures performed, (ii) a positive control group with a simple incision covered by sulfadiazine-impregnated dressing as a clinically established reference for local antimicrobial protection, and (iii and iv) experimental groups with an incision covered by NorC, respectively NorCB nanoporous fibers. Biocompatibility was evaluated through clinical monitoring, as well as hematological, biochemical, and immunological blood analyses. All procedures were performed in compliance with institutional ethical guidelines for animal experimentation. **Results:** Both NorC and NorCB fibers did not impair liver or kidney function, did not induce local or systemic inflammatory responses, and preserved immune defense capacity. Laboratory parameters evaluated were comparable with those of the control groups. Functionalization with boronic aldehyde had no adverse impact on these outcomes. **Conclusions:** Nor-loaded CHIT nanofibers, with or without boronic agent functionalization, demonstrate good *in vivo* biocompatibility, maintaining organ function, immune competence, and absence of inflammatory effects. These findings support their potential as localized antibiotic delivery systems and advanced wound care materials. **Keywords:** CHITOSAN NANOFIBERS, NORFLOXACIN, BIOCOMPATIBILITY, RATS, 2-BORONOBENZALDEHYDE.

INTRODUCTION

Burn injuries remain a significant global health challenge, leading to high morbidity and mortality due to infection, delayed healing, and scar formation (1). Wounds resulting from burns are particularly sus-

ceptible to microbial colonization due to the loss of the protective skin barrier, creating an ideal environment for pathogenic bacteria such as *Staphylococcus aureus* and *Pseudomonas aeruginosa* (2). Effective management of burn wounds requires dressings that not only provide a physical barrier but also deliver therapeutic agents to prevent infection and support tissue regeneration (3).

Conventional topical antibiotics have been used widely in burn care, but their effectiveness can be limited by poor penetration into tissue and the development of bacterial resistance (4). Norfloxacin (Nor), a broad-spectrum fluoroquinolone antibiotic, has demonstrated potent antimicrobial activity against Gram-negative and some Gram-positive organisms implicated in burn wound infections (5). Its mechanism of action involves inhibition of bacterial DNA gyrase and topoisomerase IV, which are essential for DNA replication (6). However, systemic use of Nor can be associated with side effects and suboptimal local concentrations, leading to interest in localized delivery strategies (7).

Advanced wound dressings based on biodegradable polymers have been developed to overcome these limitations by enabling sustained local delivery of antibiotics directly at the wound site (8). Among these polymers, CHIT, a deacetylated derivative of chitin, has attracted considerable attention due to its inherent biodegradability, biocompatibility, and intrinsic antimicrobial and hemostatic properties (9). CHIT can also promote cell proliferation and tissue regeneration, making it an attractive matrix for wound healing applications (9).

Electrospun CHIT nanofibers provide a structural architecture that mimics the extracellular matrix, enhancing cell attachment and facilitating gas exchange while also serving as a reservoir for drug loading and sustained release (10). The incorporation of Nor into CHIT nanofibers has been shown to improve localized antimicrobial efficacy and reduce infection in animal models of wound healing (11). Furthermore, CHIT-based nanofiber dressings have demonstrated improved outcomes compared to conventional gauze or hydrocolloid dressings in terms of infection control and accelerated re-epithelialization (12

Despite progress in the development of polymeric wound dressings, there remains a need for further optimization of antibiotic delivery systems that balance controlled drug release with minimal systemic exposure and maximal therapeutic effect at the injury site (13). By integrating advanced polymer science with antimicrobial therapeutics, innovative biomaterials such as Nor-loaded CHIT nanofibers hold promise for improving burn wound management and patient outcomes.

The **aim** of this research was to evaluate biodegradable CHIT-based nanoporous systems loaded with Nor for topical delivery, assessing their *in vivo* biocompatibility, biodegradability, and potential to provide sustained antimicrobial and anti-inflammatory effects.

MATERIALS AND METHODS

Substances. Norfloxacin (≥98%), Chitosan (126 kDa, 97%), poly(ethylene oxide) (1000 kDa), acetic acid (≥99%), 2-boronobenzaldehyde (97%), ethyl alcohol (98.89%), sodium hydroxide (95%) were purchased from Sigma-Aldrich Chemical Co (Steinheim, Germany). 2-boronobenzaldehyde (boronic aldehyde) was purified by column chromatography, and ethanol was dried over molecular sieves prior

to use.

Preparation of composite nanofibers. The composite nanofibers were prepared through a multistep process that included the fabrication of mesoporous CHIT fibers, the incorporation of Nor, and subsequent surface functionalization via imine bond formation with boronic aldehyde.

CHIT was initially subjected to alkaline hydrolysis according to established protocols reported in the literature. Porous CHIT-based fibers were subsequently produced by electrospinning a 2.1% (w/v) chitosan/poly(ethylene oxide) blend (2:1, w/w) prepared in 80% acetic acid, using a NanoSpinner StarterKit. The poly(ethylene oxide) fraction, serving as a sacrificial component, was selectively removed by immersion in 5% sodium hydroxide solution for 2 hours. The resulting fibers were thoroughly rinsed with distilled water until neutral pH was achieved, leading to the formation of a porous fibrous network. Drug incorporation was carried out by equilibrium absorption. In brief, around 400 mg of the prepared fibers were placed in 500 mL of a saturated Nor solution and kept under sealed conditions for 24 hours to allow loading.

Following drug uptake, the fibers were recovered and allowed to dry at ambient conditions, followed by further drying under vacuum. The amount of incorporated antibiotic was determined by UV-Vis spectroscopy, using absorbance readings at 272 nm and quantification based on a previously established calibration curve.

For surface modification, the drug-loaded fibers were treated with a 0.28% ethanolic solution of boronic aldehyde (10 mL per 305 mg of fibers), maintaining a glucosamine-to-aldehyde molar ratio of 10:1. This treatment promoted the formation of dynamic imine bonds on the fiber surface.

FTIR measurements were performed to examine the chemical structure of the nanofibers and to verify the presence of newly formed interactions. Spectra were acquired in ATR mode using a VERTEX 70 FT-IR spectrophotometer (Bruker, Karlsruhe, Germany) over the 4000–600 cm^{-1} range, with 32 scans recorded at a resolution of 4 cm^{-1}. The resulting data were processed using OPUS 6.5 software.

Two distinct nanofibrous systems were thus obtained: NorC, consisting of CHIT fibers loaded with Nor, and NorCB, representing the corresponding fibers additionally modified through imination with the boronic aldehyde.

In vivo **biocompatibility evaluation.** The study was conducted using healthy, pathogen-free, non-genetically modified Wistar rat (300–350 g), obtained from the university bio base and originally sourced from the Cantacuzino National Medico-Military Institute for Research and Development. Prior to experimentation, the animals were allowed a 24-hour acclimatization period and were housed individually under controlled environmental conditions (21±2°C, 50-70% relative humidity, 12 h light/dark cycle), with ad libitum access to standard diet and water. To minimize chronobiological variations, all experimental procedures were consistently performed between 08:00 and 12:00.

The experimental protocol comprised four groups: a negative control group (Negative C), with no intervention; a positive control group (Positive C), in which a standardized incision in the right flank region was treated with a sulfadiazine-

containing dressing as a reference for antimicrobial protection; and two experimental groups in which a similar-sized incision was performed in the same anatomical area (right flank), followed by application of NorC and NorCB nanofibers, respectively, as dressings.

In vivo biocompatibility was evaluated through the analysis of hematological, biochemical, and immunological parameters. Biochemical markers included liver function indicators (alanine aminotransferase – ALT, aspartate aminotransferase – AST, and lactate dehydrogenase – LDH) and renal function markers (urea and creatinine). Hematological assessment comprised leukocyte differentials, including polymorphonuclear neutrophils (PMN), lymphocytes (Ly), monocytes (M), eosinophils (E), and basophils (B). Additionally, immune function was assessed by measuring complement activity and the phagocytic capacity of peripheral blood PMN (NBT%), providing insight into potential systemic toxicity and immune response following treatment.

Blood samples were collected from the lateral tail vein. To minimize stress, animals were gently restrained, and the tail was briefly warmed to promote vasodilation. After local disinfection, approximately 0.3 mL of blood was drawn for analysis. Sampling was performed at two defined time points: 24 hours and 7 days after the surgical procedure and application of the test materials.

Ethical aspects. The experiments were carried out at the CEMEX Laboratory - Advanced Research and Development Center for Experimental Medicine Ostin C Mungiu, Grigore T. Popa University of Medicine and Pharmacy, Iași, following approval from the University Ethics Committee (Certificate No. 160/04.03.2022) and in strict accordance with national regulations (15) and international guidelines on the use of laboratory animals (16).

At the end of the experiments, the animals were humanely euthanized under general inhalation anesthesia with isoflurane (3% induction) using a veterinary open-circuit system (Komesaroff Mark 5, Kruuse, Odense, Denmark).

Statistical analysis. Data were analyzed using SPSS version 17 (IBM Corp., Armonk, NY, USA). Group comparisons were conducted primarily with one-way ANOVA, followed by Tukey's post hoc test when significant differences were observed. Results are reported as mean ± standard deviation (S.D.).

For comparisons between two groups, Student's t-test was applied, or the nonparametric Kruskal-Wallis test when assumptions of normality or homogeneity of variance were not met. Correlations were evaluated using Pearson's coefficient for parametric data and Spearman's rank correlation for nonparametric data. Simple and multiple linear regression analyses were performed to assess the influence of independent variables on dependent outcomes. Statistical significance was defined as $p < 0.05$.

RESULTS

Porous CHIT-based nanofibers incorporating Nor at a concentration of 4.35% were successfully obtained, alongside porous CHIT nanofibers loaded with Nor and subsequently iminated with 10% boronic aldehyde (17). The antibiotic was introduced into the fibers by immersion, ensuring an effective loading process. Further

surface functionalization was achieved through the formation of dynamic imine bonds with a bioactive boronic aldehyde, reaching an imination degree of 10%, which provides a suitable balance between antimicrobial activity and biocompatibility. FTIR analysis confirmed the successful incorporation and good encapsulation of the antibiotic within the nanofibrous matrices (17).

Direct visual inspection of the incision site covered with the investigated dressings did not reveal any visible local changes. No signs of inflammation, redness, edema, or other macroscopic alterations were observed.

TABLE I.

The effects of NOR-loaded nanoporous systems on the percentage values of leukocyte formula components.

	Time points of evaluation	Leukocyte formula components (%)				
		PMN	Ly	E	M	B
Negative C	24 hours	27.8±4.21	68.2±7.67	0.3±0.01	3.5±0.2	0.2±0.01
	7 days	27.2±3.52	68.6±8.13	0.4±0.01	3.6±0.2	0.2±0.03
Positive C	24 hours	27.3±2.67	68.7±7.21	0.3±0.03	3.5±0.1	0.2±0.01
	7 days	27.8±3.55	68.2±7.45	0.4±0.01	3.4±0.1	0.2±0.01
NorC	24 hours	26.8±4.27	69.1±8.33	0.5±0.1	3.6±0.1	0.2±0.03
	7 days	27.1±3.45	68.9±8.17	0.4±0.03	3.4±0.2	0.2±0.01
NorCB	24 hours	26.7±4.17	69.3±8.43	0.3±0.1	3.5±0.1	0.2±0.03
	7 days	27.2±4.25	68.7±7.67	0.3±0.05	3.6±0.1	0.2±0.01

Values are expressed as the arithmetic mean ± S.D. of the mean for five animals per group.

The distribution of PMN and Ly in blood samples from animals treated with NorC and NorCB remained consistent with that observed in both the Negative Control and Positive Control groups across all time points assessed (tab. I).

Likewise, the relative proportions of E, M and B in these treatment groups showed no significant deviations from the values recorded in the control groups throughout the duration of the experiment (tab. I). These results indicate that administration of the Nor-loaded nanoporous systems did not disrupt leukocyte homeostasis or induce detectable alterations in the overall composition of circulating immune cells.

Administration of the Nor-loaded nanoporous systems did not produce statistically significant changes in plasma levels of ALT, AST, or LDH at either 24 hours or 7 days post-treatment (tab. II). The measured enzyme levels in these groups remained comparable to those observed in both the Negative Control and Positive Control groups, indicating that the nanoparticle formulations did not induce detectable hepatocellular injury or general cytotoxicity within the observed timeframe.

No significant changes were observed in plasma urea or creatinine levels in animals treated with NorC and NorCB compared with both the Negative Control and Positive Control groups at any of the evaluated time points (tab. III). These findings suggest that administration of the Nor-loaded nanoporous systems did not impair renal function or induce detectable nephrotoxicity during the course of the experiment.

TABLE II.

The effects of Nor-loaded nanoporous systems on the blood values of ALT, AST, and LDH

	Time points of evaluation	ALT (U/L)	AST (U/L)	LDH (U/L)
Negative C	24 hours	46.82±5.33	122.24±22.29	1289.24±115.17
	7 days	49.11±4.67	123.46±20.17	1291.45±121.21
Positive C	24 hours	48.37±4.55	121.62±21.52	1292.18±122.43
	7 days	48.55±4.41	123.18±23.67	1288.35±120.11
NorC	24 hours	47.26±4.17	122.34±22.21	1290.12±117.07
	7 days	48.38±5.82	124.54±22.45	1294.25±119.55
NorCB	24 hours	47.42±5.21	120.12±21.33	1287.42±122.82
	7 days	48.16±4.63	123.28±22.19	1293.37±118.67

Values are expressed as the arithmetic mean ± S.D. of the mean for five animals per group.

TABLE III.

Effects of Nor-loaded nanoporous systems on serum urea and creatinine levels

	Time points of evaluation	Urea (mg/dL)	Creatinine (mg/dL)
Negative C	24 hours	41.28±5.17	0.15±0.01
	7 days	42.42±4.43	0.16±0.03
Positive C	24 hours	42.64±4.55	0.16±0.01
	7 days	43.36±4.21	0.15±0.01
NorC	24 hours	43.25±4.13	0.16±0.01
	7 days	43.52±5.07	0.17±0.01
NorCB	24 hours	43.16±3.67	0.16±0.01
	7 days	44.38±4.11	0.16±0.03

Values are expressed as the arithmetic mean ± S.D. of the mean for five animals per group.

TABLE IV.

Effects of Nor-loaded nanoporous systems on serum complement activity and the NBT%

	Time points of evaluation	Complement (UCH_{50})	NBT (%)
Negative C	24 hours	51.34±4.45	13.34±1.43
	7 days	52.46±4.21	14.62±1.67
Positive C	24 hours	51.72±5.17	13.74±2.17
	7 days	53.68±4.55	14.26±1.82
NorC	24 hours	52.24±4.43	13.68±2.21
	7 days	53.18±5.15	13.46±1.29
NorCB	24 hours	53.25±4.33	14.24±1.41
	7 days	53.52±4.67	14.12±1.55

Values are expressed as the arithmetic mean ± S.D. of the mean for five animals per group.

In animals treated with NorC and NorCB, serum C levels showed no significant changes compared to the Negative Control or Positive Control groups. Measurements at both 24 hours and 7 days post-treatment were comparable across all groups, indicating that the treatments did not affect C activity (tab. IV). Similarly, the NBT% values, which reflect the oxidative burst capacity of neutrophils, remained similar to those of the control groups at both time points. Overall, these findings suggest that NorC and NorCB treatments did not induce detectable effects on these immune-related blood parameters (tab. IV).

DISCUSSION

Due to its unique biochemical features and natural ability to act against bacteria, chitosan has been widely studied for use as a wound item that brings support against infections. The successful fabrication of porous CHIT-based nanofibers incorporating Nor, as well as fibers further functionalized with boronic aldehyde, highlights the versatility and potential of this system for localized, controlled antibiotic delivery. The combination of efficient Nor loading and surface imination appears to provide an optimal balance between antimicrobial efficacy and biocompatibility, which is critical for wound healing applications.

Scaffolds help keep cells at the wound area and support them in growing, moving, and changing into different types of cells inside their three-dimensional structures. Effective wound-healing scaffolds must exhibit biocompatibility, biodegradability. Among the scaffolds, nanofiber scaffolds have become very popular because they have a large surface area compared to their size, lots of tiny spaces, and the ability to carry different types of substances.

The stable incorporation of Nor within the nanofibrous matrices suggests that the fibers can act as reservoirs for sustained drug release, providing a prolonged therapeutic effect at the wound site. This sustained release is particularly advantageous for minimizing dosing frequency and reducing systemic exposure, thereby lowering the risk of systemic toxicity. The controlled functionalization of the fiber surface with boronic aldehyde may further enhance local bioactivity by promoting favorable interactions with tissue components or modulating the release profile, without triggering adverse inflammatory or cytotoxic responses.

The absence of visible local inflammation, edema, or macroscopic tissue alterations in the treated regions strongly supports the compatibility of these materials with biological environments. This observation indicates that the fibers are well tolerated by surrounding tissues and unlikely to provoke detrimental immune reactions.

In vivo evaluation demonstrated that Nor-loaded nanoporous CHIT systems maintain excellent biocompatibility and biodegradability when applied directly over rat lesions. Importantly, no significant alterations in hematological, biochemical, or immunological parameters were observed, underscoring minimal systemic toxicity and confirming a favorable safety profile for these materials as localized drug delivery platforms (18, 19).

CHIT, a naturally biodegradable and biocompatible polymer, has been extensively employed in wound healing and drug delivery due to its intrinsic non-toxic nature, mucoadhesive properties, and capacity to

support cellular adhesion, proliferation, and tissue regeneration (20). The high surface area, porosity, and interconnectivity of nanofibrous CHIT matrices not only facilitate efficient loading of therapeutic agents such as Nor but also allow for controlled and sustained release, which can be further tuned through surface functionalization.

Previous studies have delineated that Nor-loaded CHIT nanofibers enhance local antimicrobial activity while maintaining compatibility with host tissues (17, 21), consistent with the biological responses observed in our study.

These findings collectively indicate that CHIT-based nanofibers can provide an effective combination of localized antibiotic therapy, tissue regeneration support, and minimal adverse responses, positioning them as promising candidates for advanced wound management and targeted drug delivery applications (22, 23).

The absence of significant systemic inflammation or organ dysfunction in our experimental animals is consistent with previous studies in which electrospun CHIT/Nor scaffolds did not alter liver or kidney function markers in treated rats. This suggests that the embedding of Nor within a CHIT matrix does not interfere with systemic immune homeostasis or provoke adverse organ-specific effects, which is critical when considering potential clinical applications (22, 23). The maintenance of stable hematological and biochemical parameters indicates that the localized release of Nor from the nanofibers provides effective antimicrobial action at the wound site without triggering systemic inflammatory responses or organ stress.

Beyond systemic safety, CHIT nanofibers loaded with Nor have been reported to promote wound healing and tissue regeneration while simultaneously reducing infection and local inflammation (23, 24). These effects are likely mediated by a combination of the intrinsic biocompatibility and mucoadhesive properties of CHIT, which support cellular adhesion, proliferation, and extracellular matrix deposition, together with the sustained local release of Nor, which limits bacterial colonization and inflammatory signaling. The biological responses observed in our study are in strong agreement with those previously reported, reinforcing the concept that CHIT-based antibiotic delivery systems can integrate safely with mammalian tissues and actively contribute to the wound healing process.

A key aspect of this system is the controlled release of Nor from the biodegradable polymer matrices. By modulating the porosity, fiber diameter, and surface chemistry of the CHIT nanofibers, drug release can be sustained over time, maximizing local antimicrobial effects while minimizing systemic exposure and the associated risks of toxicity or dysbiosis. This controlled delivery approach ensures that therapeutic concentrations of Nor are maintained at the wound site for prolonged periods, improving infection control and reducing the need for repeated dosing.

Our observations corroborate previous reports (17, 25), demonstrating that CHIT-based nanofibers can maintain the therapeutic efficacy of Nor without eliciting systemic toxicity, thereby supporting their potential as safe and effective platforms for localized antibiotic therapy in clinical settings.

CONCLUSIONS

The present study demonstrates that NorC and NorCB, exhibit excellent *in vivo*

biocompatibility after administration in rats. Covering the skin lesion with these nanofibers did not impair liver or kidney function, did not trigger local or systemic inflammatory responses, and preserved immune defense capacity. The addition of boronic aldehyde did not negatively affects these outcomes. When compared to standard wound treatments, including a sterile dressing and a sulfadiazine-impregnated dressing as a positive control, NorC and NorCB fibers showed comparable safety and tolerance.

These findings support the potential of CHIT-based nanofibers as localized antibiotic delivery systems for advanced wound care, offering controlled release of Nor while maintaining tissue compatibility and systemic safety. Furthermore, the previously established fabrication and characterization of these fibers by our research team provide a validated foundation for their further preclinical and translational evaluation.

NorC and NorCB nanofibers represent promising candidates for innovative wound management strategies, combining antimicrobial efficacy with biodegradability, biocompatibility, and immune safety.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest.

DNA EXTRACTION FROM PLAIN SALIVA: ADVANTAGES AND LIMITATIONS (Abstract): Sufficient and good quality DNA can be extracted from a variety of biological samples. In most cases, peripheral blood is the preferred source of cells. As blood harvesting is an invasive method that should be performed by trained personnel and in designated facilities, alternative DNA sources are increasingly considered. Saliva represents an important choice, and this is reflected by the growing number of commercially available saliva collecting kits. Besides being extremely easy to use, ship and store, such kits include various stabilizers and hence offer the advantage of remarkable stability of the product. However, the cost of such devices can be prohibitive. Under the circumstances, we have used plain saliva for DNA extractions. Manual extraction using silica columns and magnetic-based automated extraction were both used and compared in terms of DNA yield and purity. The DNA integrity and potential contamination with non-human DNA was also checked in human based primers PCR reactions. Furthermore, the saliva stability was checked by incubating the samples for various periods of time. We were thus able to demonstrate that plain saliva can generate adequate amounts of pure DNA, which can be used successfully in molecular biology techniques. However, in the absence of stabilizers, the samples' stability is limited, hence they should not be stored for more than 24 hours at 4°C and they should be used for extraction within this interval. **Keywords:** PLAIN SALIVA, BLOOD DNA EXTRACTION, PCR, SALIVA STABILITY.

DNA is a biological material required nowadays for an increasing number of investigations. As a vast set of molecular biology techniques require DNA, it is not surprising that we witness a continuous development of various DNA extraction methods, able to ensure not only sufficient amounts, but also able to avoid contamination risks, thus yielding good quality material that will further generate accurate and reliable results.

A constant interest could be noticed in the recent years for the development of various methods of DNA extraction from saliva, reflected by the number of commercial kits offered by various manufacturers. Saliva is considered as an important alternative to the classical invasive approaches targeting peripheral blood or, sometimes, solid tissues. Most of the laboratories involved in molecular biology investigation of human DNA, dealing either with patients

or with healthy persons, as notably is the case for the stem cell registries, or healthy solid organ donors, prefer the peripheral blood and there are solid arguments favoring this choice. The nucleated cells within the blood stream are generally present in sufficient numbers to offer the possibility to extract good quality DNA, in reasonable amounts, that can be further directly used for most regular techniques such as PCR (Polymerase Chain Reaction) amplifications, hybridizations, sequencing or digestions. Furthermore, both blood harvesting and blood DNA extraction are long time standardized, guidelines and standard operating procedures being clearly implemented as part of accreditation procedures (1). However, harvesting peripheral blood is an invasive method, coming with certain risks of hemorrhage and infection, lack of compliance on behalf of certain patients or harvesting difficulties when veins are very small (as is the case for children), difficult to access or fragile. The procedure must be executed by specialized personnel, in adequate facilities. If such a facility is different from the laboratory that performs the DNA extraction, then transportation issues occur. Blood shipment is also strictly regulated and requires, for the biological product stability, temperature and adequate packaging conditions that not all transporters are able to fulfill, especially when samples must travel long distances to the destined center (2).

These are, in fact, some of the major reasons that lead to the pressure of identifying alternative, non-invasive methods of nucleic acids extraction. Saliva was one of the first choices as the harvesting is extremely comfortable for most individuals, and easily accepted especially by children. Furthermore, the procedure not only that it does not require medical assistance, but it can even be performed at home.

It is important to stress that cells are present in abundant amounts in the salivary fluid. Some of these cells are desquamated epithelial cells and it was considered for long time that, since they are considerably numerous (approximately $4x10^5$/mL and they continuously replenished due to the fast turn-over that renews at every 3 hours the surface layer (3), the epithelial cells should also represent the main source of DNA (4).

However, we were able to show that commercial DNA extraction kits dedicated for saliva are in fact targeting leukocytes (5) that are directed by the immune system to the oral cavity to efficiently fight against the remarkable number of pathogens that reside here (6). Our data demonstrated striking similarities between the DNA concentrations generated by peripheral blood and saliva, which allowed us to reinforce the existent parallel between the number of blood and saliva leukocytes (5).

One of the initial major concerns regarding the extraction of nucleic acids from saliva was the potential contamination of the human material especially with bacterial DNA, due to the vast presence of these pathogens in the oral cavity. Numerous studies, including ours, clearly demonstrated that the commercial harvesting kits, regularly including reagents dedicated to removing pathogens and to stabilizing the DNA, are designed such as they can generate pure enough human material, that can be successfully used in large array of techniques, from simple PCR amplifications to the sophisticated High throughout Sequencing (5, 7-10).

Another key issue that manufacturers constantly stress is the remarkable stability of the saliva fluid, and data included in the commercial leaflets show that after an in-

cubation of 187 days, at 50^0C, saliva was still able to generate non-degraded DNA, due to the stabilizers included in the harvesting kits (11).

Despite the many obvious advantages regarding non-invasiveness, DNA yield, less stringent transportation conditions, superior stability of the sample as compared to blood, saliva harvesting is still not a method of choice for most of our laboratories. Besides the lack of trust, or lack of awareness, one possible explanation resides in the relatively high cost of the commercial harvesting devices.

Under these circumstances, we have decided to attempt DNA extraction from plain saliva, harvested in regular 15 mL tubes, without any added buffers, and to characterize the efficiency of this procedure, mainly as the stability of the product concern.

MATERIAL AND METHODS

Saliva harvesting

Saliva and blood were harvested from healthy volunteers. After gently massaging their gums, they were asked to spit in a 15-mL tube a volume of approximately 2 mL. No other substances were further added to the plain saliva. Blood was extracted on anti-clotting agents (Na citrate or EDTA but not heparin, as we wanted to further check the DNA in various PCR reactions).

DNA extraction

Several different approaches and commercial DNA extraction kits are nowadays available. We have considered two such methods, a manual and an automated one.

For the manual method we have used the Invitrogen mini blood kit (Invitrogen, Life Technologies, Carlsbad, CA, USA), based on enzymatic cell lysis, 100% ethanol DNA precipitation, followed by the binding of the released DNA to a silica matrix in the presence of a high salt concentration solution. For both blood and saliva, we have used 200 µL of the respective sample and the DNA was eluted with 200 µL elution buffer.

For the automated method we have used the iPrep™ PureLink™ gDNA Blood Kit (Invitrogen, Life Technologies, Carlsbad, CA, USA). This system is based on 1 µm magnetic beads coated with a silica surface that enables them to bind the DNA. The beads are incubated with the mixture resulted from cell lysis and protein digestion. Further, they are then separated with a magnet, washed and then the DNA is eluted from the bead surface with 200 µL elution buffer. The protocol was optimized for a volume sample of 350 µL, the same procedure being employed for both blood and saliva.

DNA quantification

10 µL of the DNA solution were diluted with 90 µL of water and the DNA concentration was assessed by measuring the absorption at 260 nm with a Beckman Coulter DU800 spectrophotometer. Simultaneously, the potential protein contamination was assessed by measuring the absorption at 280 nm as well. A 260/280 ratio in between 1.8 and 2.1 was considered acceptable and the DNA pure enough to allow its usage for PCR amplification and hybridization.

PCR and hybridization

Some of the DNA samples were checked in PCR reactions as previously described (Cianga et al., 2016). Due to its simplicity, we have considered a commercial single pair primers BAG kit (BAG Health Care GmbH, Lich, Germany), optimized for 10 µL reaction volume. Should a positive reaction occur, besides a 1070 base

pairs (bp) control band, one should visualize a 420/85 bp amplicon as well.

RESULTS

The saliva samples were harvested from ten apparently healthy individuals in sterile tubes, with no additives, according to the procedure previously described. At the same time, blood was also harvested on an appropriate anti-clotting agent and DNA was then extracted simultaneously, immediately after harvesting. The DNA concentration and purity were checked by measuring the 260/280 nm absorption.

The blood DNA was extracted using only the manual method, while the saliva DNA was extracted using both the manual and the automated method. The results presented in Table I show that some of the saliva samples yielded higher DNA concentrations than the blood. The average DNA concentration for blood was 36.44 µg/mL (Standard Deviation SD-5.53) while for saliva was 47.43 µg/mL (SD-21.81, heavily influenced by sample #7 which generated a very small yield). We have also wanted to check the efficiency of the automated DNA extraction as compared to the manual one. As for the automated extraction the method was standardized for 350 µL instead of 200 µL, we have adjusted the values accordingly.

TABLE I.
DNA concentrations yielded by blood and plain saliva

Sample	Blood Manual extraction Concentration (µg/ml)	Saliva Manual extraction Concentration (µg/ml)	Saliva Automated extraction Concentration (µg/ml)	Saliva Automated extraction Adjusted concentration (%57) (µg/ml)
1	45.43	42.19	81.13	46.2441
2	38,.22	41.85	84.4	48.108
3	39.85	45.37	80.02	45.6114
4	38.41	36.62	63.24	36.0468
5	28.38	38,45	65.44	37.3008
6	40.55	62.61	73.28	41.7696
7	29.46	16.1	44.35	25.2795
8	38.57	89.23	102.14	58.2198
9	35.43	64.73	83.32	47.4924
10	30.12	28.18	38.12	21.7284
Average	36.44	47.43	71.54	40.78
SD	5.53	21.81	19.34	11.02

The manual and the automated method of DNA extraction from saliva show comparable efficiency, with a 47.43 µg/mL average yield for the manual method and 40.78 µg/mL average yield (after adjustment) when using the automated one, but sometimes with considerable differences between them. Furthermore, the DNA yields generated by peripheral blood and saliva are as well comparable, showing that

saliva can represent a viable alternative to blood.

The DNA purity was also assessed by measuring the 260/280 nm ratio (tab. II).

TABLE II

DNA purity and protein contamination assessed by the 260nm/280 nm ratio of absorption

Sample	Blood	Saliva Manual extraction	Saliva Automated extraction
1	1.89	1.79	1.91

10	1.96	1.87	1.91
Average	1.935	1.894	1.961
SD	0.081000686	0.070898989	0.057629082

The ratios shown in Table II demonstrate that extraction from plain saliva generates pure DNA that can be considered for various molecular biology techniques.

The saliva samples were then split in two aliquots which were incubated for a month at 4°C and at room temperature (RT) respectively. After this interval the DNA concentrations were measured again, and the results are shown in Table III.

TABLE III.

DNA concentrations after 30 days incubation

Sample	Saliva Manual extraction Day 0	Saliva Manual extraction 30 days, 4°C	Saliva Manual extraction 30 days, RT
1	42.19	15.69	8.4
2	41.85	15.31	9.31
3	45.37	16.53	9.83
4	36.62	11.96	7.05
5	38,45	10.98	9.6
6	62.61	11.66	7.34
7	16.1	12.4	8.46
8	89.23	23.54	17.88
9	64.73	14.21	8.73
10	28.18	15.47	8.49
Average	47.43	14.77	9,5
SD	21.81	3.64	3.07

The one-month incubation of the plain saliva leads to a remarkable decrease of the recorded concentrations, even if the samples were kept at 4°C. Table IV presents

the effect of the 30 days incubation upon the 260/280 ratio.

TABLE IV

DNA purity and protein contamination assessed by the 260nm/280 nm ratio of absorption after 30 days incubation

Sample	Saliva, Day 0	30 days, 4^{0}C	30 days, RT
1	1.72	1.63	1.66
2	1.92	1.78	1.8
3	1.9	1.81	1.75
4	1.94	1.66	1.66
5	1.95	1.71	1.61
6	1.96	1.7	1.66
7	1.85	1.7	1.7
8	1.94	1.92	1.90
9	1.89	1.65	1.7
10	1.87	1.81	1.71
Average	1.894	1.737	1.724
SD	0.070899	0.090927	0.107414

The 260/280 nm ratio is also dropping after a month incubation. However, somehow surprisingly, these ratios do not decrease as dramatically as the DNA concentration.

Given the considerable decrease in DNA concentration over the one-month incubation interval, we have decided to investigate a new batch of samples, which were further incubated for 72 hours, at 4°C. The extraction was performed automatically, and the concentrations are presented in Table V.

TABLE V

DNA concentrations yielded by plain saliva

	Concentration µg/ml		
Sample	**Saliva Day 0**	**Saliva, 48 h, 4°C**	**Saliva, 72 h, 4°C**
1	47.79	30.35	23.85
2	14.41	13.88	9.03
3	19.22	15.02	8.24
4	46.99	27.07	15.02
5	78	43.28	17.45
6	25.35	19.06	10.36
7	24.44	23.03	18.89
8	23.85	17.61	10.14
9	72.8	71.24	53.38
10	35.99	23.11	15.16
Average	38.84	28.36	18.15
SD	22.2	17.36	13.33

The initial DNA concentrations were again more than satisfactory, with an average yield of 38.84 µg/mL (SD-22.2), but steadily decreasing even when the saliva was incubated at 4°C.

The DNA purity was checked likewise,

and the results are presented in Table VI.

Only minor modifications of the 260/280 nm ration are observed across the 72 hours interval, thus confirming the results generated by the previous batch of samples.

To further verify the quality and integrity of the DNA extracted from plain saliva, we have chosen to use in a PCR reaction the samples harvested in the second batch and which were incubated for 48 hours at 4°C. The DNA volume used in each 10 μL PCR reaction was adjusted to an amount of 30 ng/reaction to meet the manufacturer's indications.

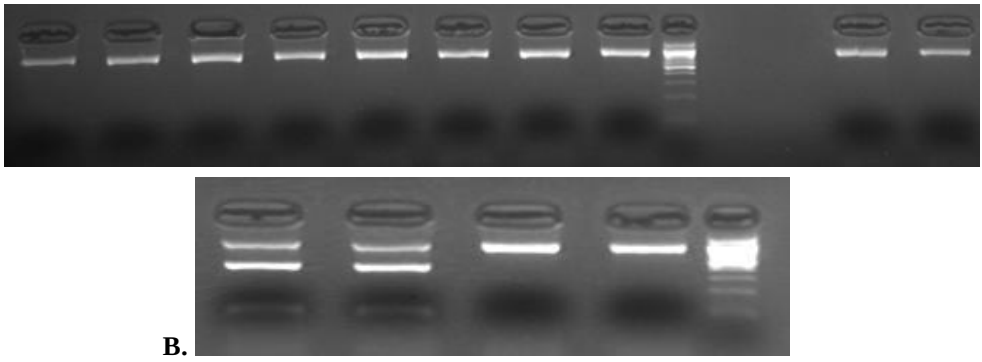

Fig. 1. A. The PCR amplification of DNA extracted from plain saliva of ten healthy volunteers, with primers for HLA-B*27, do not evidence any positive samples. **B.** PCR amplification, under the same conditions, of the DNA extracted from the peripheral blood of two patients suspected of ankylosing spondylitis and two healthy volunteers. The first two samples are positive for the HLA-B*27 allele as shown by the presence of a second amplicon besides the control band. The other two samples are negative for HLA-B*27.

DISCUSSION

DNA extraction from other sources than peripheral blood is no longer a novelty. In forensic medicine, all sorts of tissues are considered, and the extraction methods must consider an adequate digestion of the respective biological sample. For living patients, non-invasive approaches like plucked hair, cytobrush, mouthwash or the use of mucosal swabs are currently used by many molecular biology laboratories (12, 13).

The cytobrushes and the mucosal swabs are acknowledged for the high DNA yields they generate (3), but, in our hands, it proved rather cumbersome to standardize, as we have recorded important differences between the DNA concentrations from one sample to another (data not shown). Furthermore, this harvesting technique rather requires trained personnel and it is not recommended to be performed without supervision by the patients.

The mouthwash method seems more straightforward at first glance, but the washing solution has a high concentration of alcohol and this generates harvesting problems, especially with children (4).

Hence, we have opted for saliva as an alternative source of DNA and we have shown previously that the cells which are in fact targeted by most commercial kits are the leukocytes and not the epithelial cells (5). Two distinctive commercially available saliva harvesting devices were used, but both are based on the same principle of mixing the saliva with a stabilizing agent meant to prevent DNA degradation by various enzymes naturally present in this fluid and the bacterial growth. We were thus able to show that not only a comparable amount of DNA can be extracted from saliva, but also that the DNA is pure, and it can be further used in various molecular biology techniques (5).

Saliva harvesting is a non-invasive method, applicable not only for children or for persons with hardly accessible veins, but also of great use in studies that imply big cohorts of participants and which often require shipping the samples. It is often stressed that transporters are rather reluctant when dealing with blood, regarded as a potential highly infectious substance, requiring packaging; however, it seems they do not consider saliva as posing the same threat (2). Furthermore, the use of various stabilizers in all the commercially available saliva collecting devices leads (according to the manufacturers) to an impressive stability (several months), of this biological fluid, giving it an extra advantage when compared to blood (14).

However, one important downfall of this method has to do with the costs of the harvesting devices that reflect into the costs of the DNA extraction, sometimes to the point when laboratories tend to regard the method as cost ineffective. Hence, we have attempted to extract DNA from plain saliva, without adding any kind additives or stabilizers and we have investigated the stability of these samples.

Sequential DNA extractions were performed at harvesting time and after incubation of plain saliva for 48 hours, 72 hours and 30 days, either at 4oC or at room temperature. Besides confirming once more the correspondence of DNA yields obtained from blood and saliva (tab. I), our data show that the 30 days incubation of the saliva samples at RT led to a dramatic drop of the DNA yield (only 20% as compared to day 0 - tab. III), generating concentrations that would render this DNA useless for most of the commercial molecular biol-

ogy tests. The lack of adequate stabilizers, able to neutralize various enzymes, including DNases, proves to be crucial for the DNA stability. Furthermore, in the absence of stabilizers, the 260/280 nm ratio is also affected by incubation, but, as shown, to a lesser extent than the DNA yield.

As expected, the incubation at 4oC, proved to impact to a lesser extent the yields of DNA extracted under standard conditions, as shown for both batches of saliva, as well as for both DNA extraction methods (tab. III, tab. V).

An important concern addressing saliva as a source of DNA is the presence of countless microorganisms that might also contribute to the overall yield of nucleic acids extracted by one method or another (15). Numerous studies were able to demonstrate that, in fact, excellent quality human DNA can be extracted from saliva harvested with commercial devices and further used in various molecular biology techniques as PCR, hybridization, RT-PCR, PCR-RFLP, or Sanger and NGS sequencing (4, 5, 8-10, 15-17). However, the concerns raised by saliva untreated with any kind of microbicidal agent are still standing.

Nowadays, a variety of fluorochromes able to bind nucleic acids are available. Such dyes are often used to estimate the DNA concentration. However, contaminant nucleic acids can influence the fluorescent signal, either by increasing or decreasing it. This is one of the reasons why we have preferred to use spectrophotometry which is not only faster, but also more accurate. The nucleic acid shows a maximal absorption at a wavelength of 260 nm, while contaminating proteins show the maximum absorption at 280 nm. Thus, spectrophotometry can offer simultaneous information about the DNA concentration as well as about potential contamination with proteins. Furthermore, to double check the quality of the DNA extracted from plain saliva, we have used this DNA in a PCR reactions that can amplify only human DNA, due to the presence of a pair of primers specific to the HLA*B27 alleles. The results shown in Figure 1 demonstrate that the DNA we have managed to extract was not only sufficient, but also was not severely contaminated, so that it could be amplified without any problems in a regular PCR test.

As the DNA we have chosen to use in the PCR reaction was extracted from plain saliva which was incubated for 48 hours at 4oC, this also shows that the samples stored under such conditions and for this amount of time can be relatively safely used for DNA extraction. However, longer incubations at room temperature lead to DNA degradation to the point the samples cannot be used anymore for this purpose, as the yields are below the threshold set by most of commercial kits.

CONCLUSIONS

Plain saliva can thus represent a viable alternative to peripheral blood from several points of view. It is relatively easy to harvest, it does not require qualified personnel for the procedure and it can be performed at home. In other words, patients are not forced to present themselves into a specialized medical facility and can eventually ship the samples by mail. This aspect is of importance when dealing with large cohort studies. Also, given the fact that it is a non-invasive method, the patients' compliance is superior and their acceptance for enrolling in such studies is much higher.

Harvesting plain saliva is also a consid-

erably cheaper method as compared to the usage of commercial saliva harvesting kits, or to drawing peripheral blood.

On the down side, the saliva harvesting can prove sometimes difficult when dealing with children or elderly persons, with patient with psychiatric conditions or with xerostomia generated by an entire set of diseases, infections or treatments.

The DNA yield and quality are of outmost importance for any kind of molecular biology test or study. We were able to show that plain saliva can generate sufficient and pure enough genetic material for PCR test. However, the DNA stability is affected during incubation and temperature is also critical. Should plain saliva be used for DNA extraction, to avoid any risks, our recommendations are to perform the procedure either immediately or within a 24 hours interval; meanwhile the samples should be stored at 4oC.

If longer storage of saliva samples is needed or shipment cannot be performed under refrigerating conditions, then commercial harvesting kits, that include stabilizers, should be considered. The latter method might also represent a viable solution for sample banks as the ones of the Stem Cell Registries which requires HLA-retyping under particular conditions.

NEWS

NEW COMPOSITE GRAFT USED IN TREATMENT OF CHRONIC PERIODONTITIS

A group of researchers developed a new material composite acid citric based nano-hydroxyapatite (CA-NHA) that they studied it compared with nano-hydroxyapatite alone (NHA). This study was made on 10 patients, 6 women and 4 men with ages between 30-55 years, systemically healthy, diagnosed with chronic generalized periodontitis and contralateral intrabony pockets measuring ≥ 6mm. 33 graftable sites were selected and divided into two sites: 15 control sites were treated with NHA alone and 18 sites with CA-NHA acid formed with NHA powder with POC (Poly 1, 8 octanediol). The clinical exam using plaque index, gingival index, gingival bleeding index, pocket probing depth and clinical attachments level were measured at baseline 3, 6, 9,12 months and radiographic amount of defects fill, percentage of defect fill, change in alveolar crestal level were measured at 6,12 months. The data were analysed by Student`*s t*-test and it showed a significant decrease of clinical and radiographic parameters at the test sites at 12 months. This study demonstrates that CA-NHA can be considered a treatment for periodontal regeneration of intrabony defects. BLOCKED KNEE EXTENSION DUE TO A CYCLOPS LESION IN A TOTALLY TORN ACL WITH NO PRIOR RECONSTRUCTION. CASE REPORT

O. Andronic[*1,2], S. Aslam Joiya[1], C. Barbarosie[1,2]

BLOCKED KNEE EXTENSION DUE TO A CYCLOPS LESION IN A TOTALLY TORN ACL WITH NO PRIOR RECONSTRUCTION. CASE REPORT (Abstract): The cyclops lesion, also known as localized anterior arthrofibrosis is a widely recognized complication of anterior cruciate ligament (ACL) reconstruction that may lead to a mechanical block. In this report, we describe a rare case, where the patient was suffering from progressive loss of knee extension without having any prior surgery. An arthroscopy revealed a completely torn ACL along with the presence of a cyclops lesion. Subsequently, the patient was treated by resection of the cyclops lesion and ACL reconstruction using hamstring-tendon graft which enabled the patient to regain stability and full joint range of motion. **Keywords:** CYCLOPS LESION, KNEE ARTHROSCOPY, TORN ACL, BLOCKED EXTENSION.

Cyclops lesion is a common complication of anterior cruciate ligament (ACL) injury and is generally observed in patients with a history of ACL reconstruction. It has a nodular appearance and consists of fibrous granulation tissue. Patients suffering from a cyclops lesion usually present with blocked knee extension which often is accompanied by a click when executing passive full extension. However, we encountered a patient with progressive loss of knee extension that was diagnosed with a cyclops lesion on a completely torn native ACL, the localized anterior arthrofibrosis occurring neither after reconstruction nor on a partially torn ACL.

CASE REPORT

A 22-year-old Caucasian male presented to our hospital with limited right knee extension. His medical history revealed a right knee traumatic episode 9 week earlier while playing soccer. Although the patient experienced a slight sensation of instability, there was no considerable impact on patient's functional abilities which allowed him to return to his routine sporting activities. Subsequently, the patient described pain and "limited stretch" of his right knee which started to worsen 2 weeks prior admission to hospital. The clinical examination revealed a positive Lachman test together with the presence of an audible "clunk" when performing passive knee extension. The active

knee extension executed by the patient was blocked at 15 degrees.

An arthroscopy was carried out which showed a completely torn ACL and a cyclops lesion arising from the anteromedial bundle at its tibial insertion (fig. 1) together with a radial lateral meniscus tear (fig. 2A). The earlier onset of the meniscal damage was confirmed by the identification of another associated longitudinal lateral meniscus lesion that was already scarred (fig. 2B). The cyclops nodule had a typical appearance of chondroid fibro-proliferative tissue together with central neovascularization. A video record was also performed (fig. 3).

The patient came back for follow-up at 3, 6 and 12 months postoperatively. Clinical examination showed good stability with no excessive translation and the preservation of the full knee extension that was achieved postoperatively (0 degrees). An ipsilateral quadriceps atrophy and weaker knee flexion was encountered as expected, for which the patient was attending a rehabilitation program.

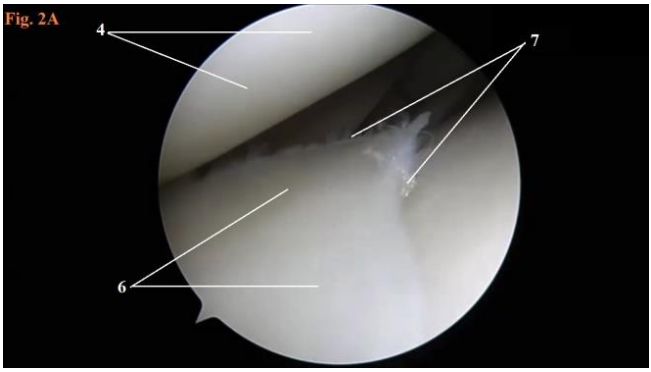

Fig. 2A. Lateral Meniscus Radial Tear (patient is placed in supine position, right knee flexed at 90 degrees, view through antero-lateral portal) 4.external femoral condyle 6. lateral meniscus 7. radial tear

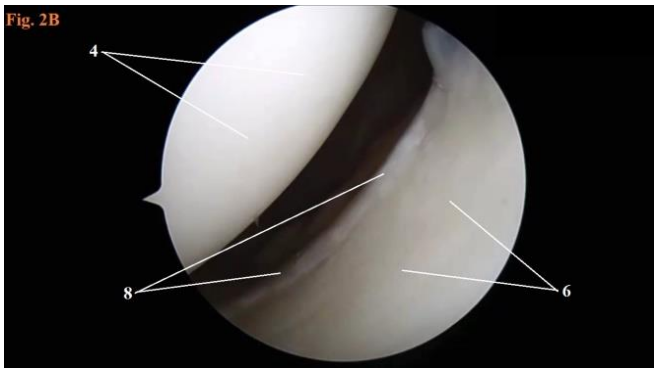

Fig. 2B. Lateral Meniscus Scarred Longitudinal Tear (patient is placed in supine position, right knee flexed at 90 degrees, view through antero-lateral portal)
4. external femoral condyle 6. lateral meniscus 8. scarred longitudinal tear

DISCUSSION

Previously published studies describe a variable incidence of cyclops lesions after ACL reconstruction ranging from 3.61% (1) to 46.8% (2). Conversely, there is limited evidence in the current literature describing cyclops lesions that occur on native ACLs with no history of surgery due to the rareness of this condition. The biggest pool of patients was recorded in 2007 which included a total of 10 patients with cyclops lesions in the absence of ACL reconstruction. (3) When investigating the etiology, recent studies have shown that a small intercondylar notch may contribute to cyclops formation (4), in addition to other already known underlying causes such as: ACL stump remnant, intra-cellular debris from the drilling of the ACL tunnels, non-anatomic tunnel placement that can lead to graft impingement (5-7). Even though measures are taken to prevent the issues, the cyclops lesion can remain clinically silent for an undetermined period and result in progressive loss of knee extension with different times of onset. This demonstrates the presence of other predisposing factors that were not determined yet. A loss of knee extension may be also encountered among the following pathologies: torn meniscus fragments, meniscus cysts or mucoid cysts, villonodular synovitis or synovial hemangioma, synovial osteochondromatosis, Hoffa's disease, osteochondritis dissecans and different tumors. In our patient, we encountered lateral chronic meniscus tears, represented by one radial tear and one scarred longitudinal tear, which possibly may have contributed to the cyclops formation, as they could cause a degree of antalgic knee flexion and predispose to fibrosis. Due to the limited number of published cases regarding this condition (8-14), we believe any addition is crucial.

CONCLUSIONS

The findings of this case report together with previous reports demonstrate that cyclops lesions should be considered among the clinical differential diagnosis in patients with blocked knee extension.

Investigating the predisposing factors might aid in the diagnosis and in minimizing the incidence of cyclops lesions as a potential complication after ACL reconstruction.

ORAL ANTICOAGULANT TREATMENT IN OBESE PATIENTS (Abstract): The prevalence of obesity is alarmingly growing worldwide, so managing the oral anticoagulant treatment in this patient category will be a day by day challenge. For warfarin, the appropriate INR monitoring and dose adjustment solve the problem of over- or under-dosing. The non-vitamin K antagonist oral anticoagulants are recommended in fixed dose regimes across different body weights. Given that certain pharmacokinetic parameters are altered in patients with morbid obesity and highlighting the serious consequences of thrombotic events, underdosing these oral anticoagulants is a real concern. We summarized the existing data, drawing attention upon the limited information on the efficacy and safety of non-vitamin K antagonist oral anticoagulant use in patients with morbid obesity and presenting a series of clinical practice guidelines for this special patient category. **Keywords:** ANTICOAGULANTS, OBESITY, ATRIAL FIBRILLATION, VENOUS THROMBOEMBOLISM.

In the last decade, the prevalence of obesity has increased rapidly in both developed and developing countries and is currently one of the most serious health problems worldwide (1). The estimations for the near future are even more alarming: until 2030, 50% of the world population will be obese and 10% will be morbidly obese (2).

The strong association between obesity and cardiovascular disease is well known (3, 4). Ischemic heart disease, stroke and venous thromboembolism (deep vein thrombosis and/or pulmonary embolism) are by far the first three most common cardiovascular diseases and important causes of morbidity and mortality in the obese patient.

In this context, the dosing of oral anticoagulants is one of the challenges physicians will face increasingly often in this continuously growing category of patients.

Some pharmacokinetic parameters are significantly altered in the obese patients. These patients have increased glomerular filtration rate and renal plasma flow by up to 51% and 31%, respectively (5) due to functional and structural renal changes and glomerular hyperfiltration. The absolute drug clearances and volume of distribution are higher in obese than in normal weight patients (6), so in obese patients shouldn't the oral anticoagulant dosage depend on both the patient and the drug? Unfortunate-

ly, many clinical trials excluded or have limited overweight patients enrolled, thus optimal dosing for both safety and efficacy of oral anticoagulants in this population is lacking.

Vitamin K antagonists (VKA)

Warfarin dosing in obese patients is not very difficult because INR directly reflects the level of anticoagulation. Thus, as warfarin is monitored, under- and over-coagulation can be prevented with appropriate INR monitoring and dose adjustment. Still, one must know that obese patients, and particularly the morbidly obese ones, have a decreased initial response to warfarin compared to the normal weight patients. Also, they require higher doses of warfarin and longer times to achieve therapeutic INR values (6 days *vs.* 8 and 10 days, respectively) (7).

Direct-acting oral anticoagulants

In the modern era of the anticoagulant treatment, four direct-acting oral anticoagulants are approved for the treatment of venous thromboembolism (VTE), prevention of VTE after total hip and knee arthroplasty and for the ischemic stroke prevention in patients with non-valvular atrial fibrillation (AF). The non-vitamin K antagonist oral anticoagulants (NOAC) are: apixaban, edoxaban, rivaroxaban (direct factor Xa inhibitors) and dabigatran (direct thrombin inhibitor). Furthermore, rivaroxaban, co-administered with acetylsalicylic acid (ASA) alone or ASA plus clopidogrel or ticlopidine is indicated for the prevention of atherothrombotic events after an acute coronary syndrome with elevated cardiac biomarkers.

NOACs exert their anticoagulant effect closely related to their plasma concentrations. The major determinants of plasma concentration of NOACs are: plasma volume (directly related to body weight), volume of distribution, degree of protein binding and renal clearance. As shown in the table below, the group of the four NOACs is quite heterogeneous (8, 9) (tab. I).

TABLE I

Pharmacokinetic profiles of the newer anticoagulant agents

	Volume of distribution (L)	Protein binding (%)	Clearance
Dabigatran	60-70	35	80% renal
Apixaban	21	87	25% renal; 75% biliary
Edoxaban	107	55	37-50% renal
Rivaroxaban	50	95	66% renal; 33% biliary

Laboratory studies conducted on small numbers of healthy volunteers demonstrate that extreme body weights have modest effects on NOAC exposure and it is unlikely to be of clinical value (10, 11, 12). None of the NOACs phase III clinical trials reported the number of patients enrolled with a body mass index (BMI) of > 40 kg m^{-2} or their clinical outcomes (13), so experience in patients with morbid obesity (> 150 kg) is very limited and there are concerns about their efficacy and safety in this patient category.

The efficacy and safety of NOACs for thromboprophylaxis in orthopedic surgery

The analysis comparing NOACs with

enoxaparin 40 mg daily for prophylaxis in orthopedic surgeries in patients with BMI > 30 kg m^{-2} (RE-MODEL, RE-NOVATE and RE-NOVATE II with dabigatran; ADVANCE-2 and ADVANCE-3 with apixaban; RECORD-1, RECORD-2, RECORD-3 and RECORD-4 with rivaroxaban) found similar rates of VTE and similar or insignificant increase in bleeding rates (13) as compared with enoxaparin. Furthermore, regarding dabigatran, the efficacy and safety were similar in each treatment group across obesity subgroups of BMI 30-35 kg m^{-2}, 35-40 kg m^{-2}, and > 40 kg m^{-2} (14).

The efficacy and safety of NOACs in patients with VTE

The recent Di Minno's meta-analysis (15) of 6 large randomized controlled trials comparing NOACs with VKA in patients with VTE included 27,023 patients, of which 20,1% had high body weight, as specifically defined in each trial (> 90 Kg in rivaroxaban trials and > 100 Kg in dabigatran, apixaban and edoxaban trials).

In terms of efficacy (prevention of VTE recurrence and VTE-related death), NOACs was like VKA in high body weight patients. Considering that the weight may not reflect the patient's actual metabolic status, the authors repeated the analyses using data on BMI and obtained similar results, thus confirming the findings of the principal analysis. These results were also confirmed when the data were stratified by NOAC type (anti-factor Xa or anti-factor IIa).

When comparing obese with normal-weight patients, the NOACs have shown non-inferiority in terms of efficacy, except dabigatran (13) in which the risk of the primary efficacy outcome was significantly higher for patients weighting > 100 kg than for patients of normal weight (50-100 kg).

In terms of safety (major or clinically relevant non-major bleeding) NOACs were comparable to VKA in high body weight patients. Because the original studies on dabigatran did not provide separate safety data according to the body weight, only anti-factor Xa drugs were included in the safety analysis, thus no stratification by NOAC type is available.

The results of this meta-analysis have clinical implications, by allowing the use of fixed doses of NOAC in patients with different body weights. However, due to insufficient data, the use of standard therapy with NOACs needs caution in patients with morbid obesity.

The efficacy and safety of NOACs for the stroke prevention in patients with non-valvular AF

Two of four AF trials have not yet published sub analyses by weight, so the available data are coming from rivaroxaban and dabigatran trials.

In an US Food and Drug Administration analysis regarding the rates of stroke or systemic embolism among patients from ROCKET-AF trial (rivaroxaban) it is stated that there is no statistical relationship between weight category (<50 kg, 50 - ≤ 70 kg, 70 - ≤ 90 kg, 90 - ≤ 110 kg, and >100 kg) and the rate of stroke or systemic embolism (16). The ROCKET-AF trial results demonstrated the efficacy of rivaroxaban 20/15 mg once daily regimen independent on BMI or body weight, so no dose adjustment according to weight category was recommended.

The analysis of pharmacokinetic data of patients enrolled in RE-LY trial pointed out that since the area under the concentration vs. time curve is not affected by body weight (10), no weight-based dose adjust-

ment is required. Another analysis of the RE-LY trial (17) categorized the patients by BMI into three subgroups: a bottom 10% (BMI of $\leq$ 22.5 kg m^{-2}), a middle 80% (BMI of 22.5 to $\leq$ 36 kg m^{-2}) and an upper 10% (BMI of > 36 kg m^{-2}). In the highest BMI group, the 1-year stroke or systemic embolism rate did not differ significantly among the treatment regimens (dabigatran 110 mg bid, dabigatran 150 mg bid or warfarin). Also, one-year bleeding / stroke or systemic embolism rates did not differ significantly between the upper and the middle BMI group (17). Still, due to the very limited clinical experience of dabigatran use in patients weighing more than 110 kg, careful clinical surveillance is recommended.

In the middle of 2016 the Scientific and Standardization Committee of The International Society on Thrombosis and Hemostasis (ISTH) published the following guidance statements regarding the use of the direct oral anticoagulants in obese patients (13):

1. Standard dosing of the NOACs is recommended in patients with a BMI $\leq$ 40 kg m^{-2} or a weight $\leq$ 120 kg for VTE treatment, VTE prevention and prevention of ischemic stroke and systemic arterial embolism in non-valvular AF;

2. NOACs should not be used in patients with a BMI of > 40 kg m^{-2} or a weight of > 120 kg, because there are limited clinical data available for patients at the extreme of weight;

3. If NOACs are used in a patient with a BMI of > 40 kg m^{-2} or weight of > 120 kg, checking the drug-specific peak and trough level is recommended. If the level is within the expected range, continuation of the NOAC seems reasonable. If the drug-specific level is found to be below the expected range, changing to a VKA rather than adjusting the dose of the NOAC is recommended.

CONCLUSIONS

We briefly presented the available data regarding the use of the non-vitamin K antagonist oral anticoagulants in obese patients, noting that neither efficacy nor safety of NOACs in the obese patients has been specifically investigated in large randomized controlled trials. Based on the existing data (from pharmacological and clinical studies), the product labeling (package inserts) of the approved NOACs does not contain a dose adjustment for high weight or BMI in obese categories. Therefore, we emphasize the importance of ISTH recommendations in the current medical practice.

MULTILOCULAR CYSTIC RENAL CLEAR CELL CARCINOMA - CASE REPORT (Abstract): MCR CCC is a rare subtype of renal clear cell carcinoma with specific morphologic and immunohistochemical features. No progression of multilocular cystic renal cell carcinoma is known. We present the case of a 56-year-old male, with an accidentally discovered renal tumor due to its unusual gross appearance and a rare clinical entity. He subsequently underwent a radical right nephrectomy and further histological examination revealed the tumor to be a multilocular cystic renal clear cell carcinoma, Fuhrman grade 2. **Keywords:** CLEAR CELL, KIDNEY, MULTILOCULAR CYSTIC RENAL CELL CARCINOMA.

Multilocular cystic renal clear cell carcinoma (MCR CCC) is a rare cystic renal tumor composed entirely of numerous cysts, the septa of which contain small groups of clear cells resembling grade I clear cell carcinoma (1). Grossly, MCR CCC consists of a well-circumscribed mass of small and large cysts filled with serous fluid and separated from the kidney by a fibrous capsule (2). The tumor has an excellent outcome and a good prognosis, having no known recurrence or metastasis (3). Histologically, the cysts are lined by a single layer of epithelial cells, usually composed of polygonal or cuboidal clear cells. Occasionally, the lining epithelium consists of several layers of cells or few small papillary structures. The nuclei are almost always small, spherical, and have dense chromatin (4). The septa consist of fibrous tissue, sometimes containing a population of epithelial cells with clear cytoplasm, resembling those lining the cysts. The tumoral stroma is also highly vascularized. MCR CCC is usually positive for CD10, vimentin, and epithelial membrane antigen (EMA) (5). We present a case of MRC CCC diagnosed incidentally, during pre-operatory CT investigation, in a 56-year-old male patient, admitted to our Hospital for aortic aneurysm management.

CASE PRESENTATION

We present the case of a 56-year-old male who was admitted to our hospital for abdominal aortic aneurysm management. The patient had a history of abdominal and lumbar pain. A pre-operatory CT scan revealed an abdominal aortic aneurysm, and a

well-defined multiseptated cystic mass in the lower pole of the left kidney. There was no evidence of left renal vein involvement nor was lymphadenopathy seen (fig. 1).

Fig. 1. Post contrast CT scan showed a multiseptated cyst in the lower pole of the left kidney

There was no family history of von Hippel Lindau syndrome or renal tumors of any kind. The biochemical assessment of the renal function was normal. Complete blood count and other preoperative investigations revealed high inflammatory markers (ESR=30mm/hr., fibrinogen= 627mg%, and CRP=17.2 mg %). Since cystic renal cell carcinoma (RCC) could not be excluded, a left-side nephrectomy was performed. The gross examination of the kidney revealed a cystic tumor in the renal lower pole measuring 48 × 40 × 30 mm. The tumor cut surface showed a multiloculated cyst with proteinaceous content, well defined margins, bulging under the renal capsule, without its involvement. No necrotic area and hemorrhagic infiltration was found in the yellowish tumor mass (fig. 2).

On histological examination, the dissected tumor specimen proved to be a multiloculated cyst consisting of cystic cavities separated by septal walls (a). The cyst wall was lined by single or multiple layers of clear cells with well-defined borders, clear cytoplasm and small hyperchromatic nuclei (Furhman nuclear grade 2) (b). No mitotic figures were seen. Focally, few cysts showed small papillary structures (c). The septa between the cysts also contain cords and clusters of similar tumor cells. Few stromal foci exhibited increased vascularity

and hemosiderin laden macrophages. No necrosis or vascular invasion was seen. The tumor did not invade the renal capsule and hilar structures (d) (fig. 3).

Fig. 2. Gross examination of the kidney revealed a multiloculated cyst in the renal lower pole

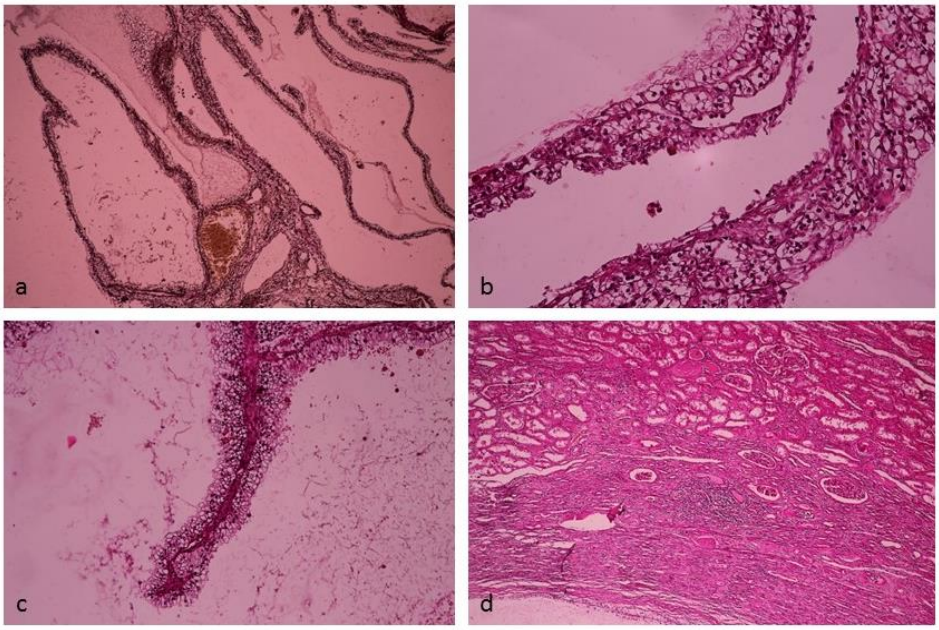

Fig. 3. Histological examination revealed cyst walls lined by one (a: EVG, x10) or multiple layers of clear cells with well-defined cytoplasmic borders and small nuclei (b: HE, x40); few cysts showed small papillary structures (c: EVG, x20); no capsule invasion was seen (d: HE, x10).

The histomorphology was compatible with MCR CCC. TNM staging and Fuhrman nuclear grading were stage T1a and grade 2, respectively.

DISCUSSION

According to the 2004 World Health Organization (WHO) classification of kidney tumors (2), MCR CCC is a rare subtype of renal clear cell carcinoma (1). 90% are discovered incidentally, on radiology for other purposes (6). MCR CCC is also known as multicystic renal clear cell carcinoma (7). The 2016 WHO classification of renal tumors (8) contains significant changes of the 2004 WHO renal tumor classification. The revision of the previous classification was performed under consideration of new knowledge on pathology (and not only), including changes of the existing renal tumor types, new renal tumors and grading system for renal tumors.

The new 2016 WHO classification refers to tumor subtypes named on the basis of predominant cytoplasmic features (e.g. clear cell RCC), architectural features (e.g. cystic RCC), anatomical tumor location (e.g. cortical RCC) and correlation with previous renal disease (e.g. acquired cystic disease-associated RCC) (8, 9).

MCR CCC is used to describe a cystic RCC composed entirely of numerous cysts, the septa of which contain a small mass (less than 25%) with no infiltrative growth (8). Microscopically, per Williamson SR et al (10), MCR CCC is a tumor consisting entirely of cysts with small groups of non-expansive clear cells in the septa. Cysts are lined by polygonal clear cells, with clear cytoplasm and low nuclear grade. Suzigan S et al (3) noted that tumoral cells are also arranged in cords, alveolar structures with small cysts and large cysts covered by a single cell layer; few tumor cells forming small papillary structures are accepted (11). In our case, the tumor histomorphology was suggestive of multicystic clear RCC with no expansive growth. Multiple publications report no recurrence or metastases in patients with MCR CCC (3. 5, 12).

As concerns renal tumors grading, the Fuhrman system was the most frequently used grading system applied to cystic RCC (13). For grade 1 to 3 tumors, the system defines tumor grade based on nuclear prominence. In our case, the tumor was composed of clear cells with low grade nuclei (Fuhrman nuclear grade 2.)

Acquired cystic RCC is a new tumor entity included in the 2016 WHO classification (8). Per Moch H et al (13), acquired cystic disease-associated RCC occurs in patients with acquired cystic renal disease, which was an unknown condition in our case.

Given the presence of cystic and papillary structures covered by clear cells, the differential diagnosis of MCR CCC consists of other cystic lesions of kidney tumors, such as renal cell carcinoma with cystic changes and clear cell papillary RCC.

While cysts are common in clear cell RCC, only rarely is the tumor entirely composed of cysts. Unlike regressing clear cell renal cell carcinoma with cystic degeneration, these cysts are filled with hemorrhage and necrosis. There are areas of expansive growth of neoplastic cells in the septa between the cysts indicating a fully malignant, clear cell carcinoma with cystic changes (12). Clear cell papillary

RCC is usually cystic and the cyst walls are lined by clear cells. However, much of the tumor exhibits papillary architecture, a feature not found in MCR CCC (14).

CONCLUSIONS

We reported this case because of its rarity and for avoiding a misdiagnosis as conventional clear cell RCC.

The limits of the paper are represented by the lack of other exams: no IMH and genetic investigations were made. The criteria for MCR CCC, defined by the 2004-2016 WHO classification of kidney tumors, were enough for diagnosis setting. The elucidation of different mutations on the onset and progression of MRC CCC will be an important future area of research. The identification of new therapeutic agents that are effective on CC RCC will be an important ongoing research topic, as well.

NEWS

NUMBER OF LYMPH NODES IN PRIMARY NODAL BASIN AND A ''SECOND LOOK'' PROTOCOL AS QUALITY INDICATORS FOR OPTIMAL NODAL STAGING OF COLON CANCER

Regional lymph node (LN) metastasis is a strong negative prognostic factor in colorectal carcinoma. The 5-year disease-free survival of patients with LN metastasis is reduced by up to 48%, depending on the T stage and the number of positive LNs, as compared to patients with nodenegative cancer. Moreover, nodal status is also a predictive factor for the efficacy of adjuvant chemotherapy that confers a definite survival benefit in stage III but not stage II carci noma. The 5-year disease-free survival in stage II colon cancer ranges from 64% to 79% depending on the T stage. Potential causes for relapse in stage II colon cancer include peritoneal involvement, lymphovascular or perineural invasion and understaging of nodal disease status that leads to a patient being inappropriately denied adjuvant chemotherapy. The critical importance of accurate LN staging has led previous studies to address the question of minimum number of LNs that need to be examined for optimal evaluation of nodal status. The recommended minimum number of LNs to be examined varies significantly across publications and ranges anywhere from 6 to 20. Others have suggested that there is no minimum threshold that can accurately stage cancer for all patients and all LNs must be examined to ensure optimal nodal staging of colon cancer resections. There are large population-based studies that do not show an association between increasing numbers of evaluated LNs and the proportion of LN-positive cancers. The current American Joint Committee on Cancer (AJCC) guidelines suggest evaluation of 10 to 14 LNs in colorectal cancer resections as a minimum standard but encourage recovery of more LNs. The Association of Directors of Anatomic and Surgical Pathology recommends that the mean number of LNs in a series of dissections should be approximately 12 to 15 and the current College of American Pathologists colorectal cancer protocol recommends that specimens be reexamined if fewer than 12 LNs are identified. Unfortunately, none of the current guidelines emphasize the importance of the location from where most LNs should be examined and the numerical threshold continues to be the only quality indicator used in current practice. The aim of the study was to evaluate distribution of positive LNs in colon cancer resections in the immediate vicinity and distant from the tumor site and to determine the proportion of cases that could be upstaged by instituting a ''second look'' protocol in all cases that were negative after the first search (Lisovsky M, Schutz SN, Drage MG, et al. Number of Lymph Nodes in Primary Nodal Basin and a ''Second Look'' Protocol as Quality Indicators for Optimal Nodal Staging of Colon Cancer. *Arch Pathol Lab Med* 2017; 141: 125-130).

ATTEMPTED SUICIDE: A CROSS-SECTIONAL SURVEY 2015 (Abstract): **Aim:** Suicide is a global health problem with an increasing incidence among young adults and teenagers. The study was aimed at analyzing the profile and identifying the frequency, nature, and contributing factors of suicides. **Material and methods:** This retrospective study included all patients who attempted suicide admitted to the Emergency Department (ED) of 'St Spiridon' Hospital Iasi - Romania, during 2015. They were analyzed by sex, age, residence, suicide method, associated pathology, potential risk factors and interventions. **Results and discussion:** The study included 368 patients (53.81% female and 46.19% male). 63.58% were admitted to ED for drug ingestion, 14.13% for ingestion of organophosphorus compounds, rat poison, herbicide and corrosive substances and 22.28% for traumatic suicide attempts. Drug ingestion (42.11%) was preferred by women while self-inflicted cut injuries (14.94%) and corrosive substance ingestion (8.42%) were more common in males. Benzodiazepines ingestion (20.10%) followed by self-inflicted cut injuries (13.85%) and corrosive substance ingestion (6.52%) were the most frequently used suicide methods. At the time of admission to ED31.52% of patients were on psychiatric treatment and 65.48% were at the first suicide attempt. The admission rate was 57% and mortality rate 0.27%. **Conclusions**: Suicidal behavior can be prevented by psychotherapeutic, pharmacological or neuromodulatory treatments for mental disorders. Also, regular follow-up of people who attempted suicide by mental health services is key to preventing future suicide attempts. **Keywords**: SUICIDE, SUICIDE METHOD, SUICIDE ATEMPT, RISK FACTORS, SELF-INFLICTED CUT WOUNDS.

Suicide is a major health problem worldwide, particularly among teenagers and young adults (1, 2, 3, 4).

Suicide attempt is the main cause of death in young people, accounting for over 50% of violent deaths (5, 6, 7, 8, 9). According to the statistics published by specialized institutions (EUROSTAT, OECD and WHO) for the years 2013 and 2014, Romania ranked ninth among the countries with the highest suicide rates (12.2 per 100,000 population), Lithuania ranked first (27.1 per 100,000 population) followed by Hungary (18 per 100,000) and Estonia (17.3 per 100,000 population) (10, 11, 13).

Per the 2008-2015 annual reports of the "Mina Minovici" Institute of Forensic Medicine, between 2,477 and 3,050 suicides were recorded annually in Romania, accounting for 25% of all violent deaths.

Analyzing the deaths registered in the last 8 years by the mechanisms of death, the most common were: mechanical asphyxia by hanging (78.62%), voluntary intoxication (7.12%) and falling (5.56%) (4, 13, 14).

MATERIAL AND METHODS

A retrospective descriptive study was conducted that included all patients who presented in 2015 (January 1 - December 31, 2015) to the Emergency Department of the Iasi "Sf. Spiridon" Hospital and were diagnosed at presentation with suicide attempt. Our study included 368 patients, 198 (53.81%)women and 170 (46.19%) men. The selection of cases was based on the diagnosis at the time of admission, positive findings on physical examination, results of laboratory tests that confirmed the ingestion of drugs or other toxic substances, patient or witness statements. Toxicological determinations were made by using a Triage Meter Pro that allows fluorescence immunochemical tests. The device is available in the ED and provides quality results fast (~15 minutes), next to the patient.

The study cases were selected per the inclusion criteria from a total of 69,232 patients admitted to the ED of the Iasi "Sf. Spiridon" hospital during the year 2015. Thus, included in the study were 368 patients aged 18 to 87. Excluded from the study were the patients under 18 years of age, patients who died before reaching the hospital, patients with accidental ingestion of toxic substance, and patients with inconclusive history.

The data collected and inserted in databases were statistically analyzed using *Microsoft Excel* and *SPSS 18.00* statistics software. Patients characteristics were expressed as the mean standard deviation or as a number and percentage.

RESULTS

Only 0.53% (368 from 69.232) of all patients presenting to the Emergency Department of the Iasi "Sf. Spiridon", Hospital during 2015 were eligible for the study (368, aged 18 to 86).

Data processing was primarily intended to identify the personal characteristics of the selected patients. It is a first starting point in strategic planning best practices. Most study patients were in the 18-30 age group (38.31%) and gender distribution showed a relatively equal distribution of subjects (53.81% women and 46.19% men, respectively), unlike the national statistics showing that the percentage of men attempting suicide was constantly higher than that of women ((82% *vs.*18%, respectively).

The sociocultural, educational and economic implications lead to an uneven distribution of cases by area of residence, 638% of the study cases being rural patients.

Regarding the suicide mechanism, 63.58% were admitted to the ED for voluntary drug ingestion, 14.13% reported intake of toxic substances (organophosphates, rodenticides, corrosives, herbicides and alcohols) and 22.28% traumatic suicide attempts (cut wounds, stab wounds, self-immolation, mechanical asphyxia by hanging and falls from heights).

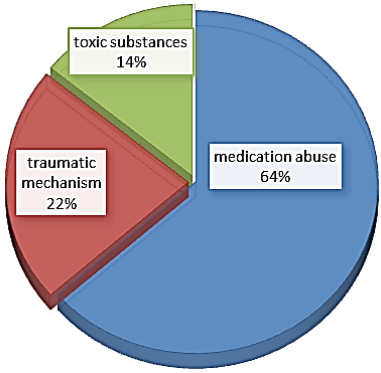

Fig. 1. Method of suicide attempt

The most common suicide method among female patients was voluntary drug ingestion (78.28%), while men preferred traumatic mechanisms (35.29%) and ingestion of toxic substances (18.23%). According to the statistical study conducted, patients in rural areas resorted much easier to ingestion of toxic substances and traumatic mechanisms, while patients in urban areas preferred drug ingestion.

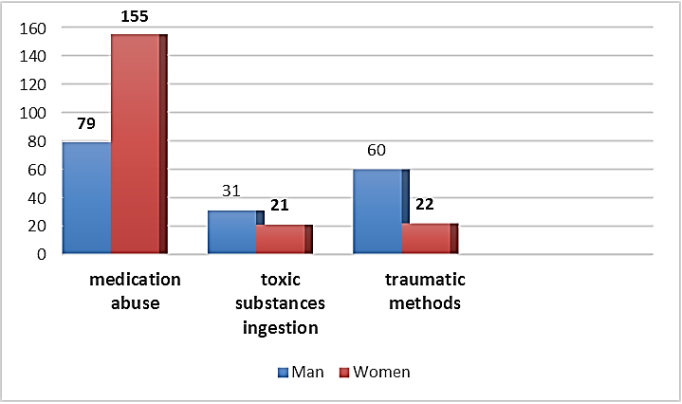

Fig. 2. Suicide method by gender

Of the patients who attempted suicide by drug ingestion, 73.07% were brought to hospital by ambulance from home, being found by the family, the average time interval elapsed between ingestion and hospital arrival being 2 to 6 hours (61.96%). 32.90% of patients used their prescribed medication for suicidal purposes.

Qualitative toxicological determinations in the ED revealed the presence of benzodiazepines in 29.67% of cases, followed by antiepileptics (17.41%) and tricyclic antidepressants (4.27%). 31.19% of patients took drugs in combination with alcohol.

In patients who ingested toxic substances, the most common were: corrosive substances (48.07%), organophosphates (21.15%), rodenticides (11.53%), toxic alcohols (7.69%) and herbicides (1.92%).

Traumatic suicide attempt was mostly preferred by male rural patients and the most common mechanisms were self-inflicted wounds (70.83%), followed by foreign body ingestion (12.5%), mechanical asphyxia by hanging (9.72%), self-immolation (2.77%) and falls from heights (2.77%). Six patients (7.31%)were imprisoned with a history of multiple suicide attempts, and sought medical care for foreign body ingestion (66.66%) and self-inflicted wounds. Per the Suicide Prevention Alliance, every year in Romania there are around 13 deaths by suicide per 100,000 inhabitants, thus ranking third in the hierarchy of violent death circumstances.

Of all the study patients 83.69% said that it was the first attempted suicide, triggered by a family conflict or pre-existing psychiatric diseases.

The average length of stay in ED was about 6 hours, during which the patients received therapy to stabilize the vital signs. Early diagnosis and initiation of specific therapy is the best way to reduce the complications that may occur.

Importance was given to medical history and physical examination. Blood and urine toxicology tests had an important

place among the biological parameters analyzed in all study patients. Throughout the ED stay, all the patients were monitored in terms of Glasgow Coma score, blood pressure, heart rate, respiratory rate, peripheral blood oxygen saturation (SatO2), temperature and diuresis. 92.94% of patients were hemodynamically stable, however 7.06% of patients required supportive care (orotracheal intubation, mechanical ventilation and positive inotropic and chronotropic agents). Also, depending on the associated pathology, patients received specialist advice (toxicology, cardiology, surgery, gastroenterology, gynecology, etc.). Simultaneously with the symptomatic treatment and detoxification the supportive therapy was initiated, by which the patients were helped to understand how and why they resorted to these methods and what they can do in the future to prevent relapse.

All patients presenting to the emergency department were stabilized. Subsequently,57% of the patients required hospital admission because of significant medical complications that required further treatment and follow-up. The remaining 43% of patients were hemodynamically stable and were referred to other hospitals, returned home or left the ED against medical advice.

Two cases (3.84%) of voluntary methyl alcohol ingestion referred to the Nephrology Clinic required hemodialysis. One death was recorded (0.27%) because of mechanical asphyxiation by hanging in a patient with pre-existing psychiatric disorder.

DISCUSSION

Comparing the rate of suicide attempts in our study with the national statistics for Bucharest, the capital municipality of Romania, reported by the "Mina Minovici" Institute of Forensic Medicine we found an equal incidence, in both cases with an average of 10% (13, 14).

Nationally, mechanical asphyxia by hanging is the most frequently used suicide method followed by voluntary drug ingestion (14) and fall from heights while in the Iasi County 63.58% reported voluntary drug ingestion and 14.13% ingestion of toxic and non-pharmacological substances for suicidal purposes and only 22.28% had attempted suicide by traumatic mechanism. As suicide mechanism women prefer drug ingestion, while men resort to more painful methods: traumatic mechanisms or ingestion of toxic substances, which can lead to a much higher death rate among men.

The time elapsed between ingestion of toxic substance and arrival at the hospital is extremely important in determining patient prognosis.

Even if worldwide suicide attempt is the main cause of death in young people, accounting for over 50% of violent deaths, in our case study one death was recorded (0.27%) because of mechanical asphyxiation by hanging in a patient with pre-existing psychiatric disorder (4, 5, 6, 7, 8, 9).

Mental disorders and physical illness may lead persons to commit suicide. In a retrospective study of suicide notes, medical and police charts of persons who committed suicide, the patients were examined at the Department of Forensic Medicine of Ludwig-Maximilians-University Munich between 2009 and 2011. The study included 1069 cases,18.9 % gave a physical disorder as reason for committing suicide and 32.7 % a medical disorder. Regarding to method of suicide, patients with mental disorders had more often previous suicidal attempts and jumping in front of a car was the most frequent method of suicide while persons with physical diseases most often

shoot themselves. Comparing to literature, in our case, 83. 69% said that it was the first attempted suicide, triggered by a family conflict or pre-existing psychiatric diseases (15).

CONCLUSION

Patients included in the study were in most of cases women, with ages less than 30 years old, from urban area, who chose as a suicide method the voluntary drug ingestion.

Suicidal acts are rarely an act of free will. In most cases, suicidal attempts are the result of untreated psychiatric disorders.

Suicidal behavior can be prevented by psychotherapeutic, pharmacological or neuromodulatory treatments for mental disorders. Also, regular follow-up of people who attempted suicide by mental health services is key to preventing future suicide attempts.

Reduced access to toxic substances (organophosphates, methyl alcohol) fighting alcoholism, early detection, treatment and medical care given to people with mental disorders and monitoring people who have experienced a suicide attempt are some steps that should be taken to prevent and reduce the size of this phenomenon.

FECAL MICROBIOTA TRANSPLANTATION IN RECURRENT NAP1/B1/027 CLOSTRIDIUM DIFFICILE INFECTION (CDI) RESISTANT TO VANCOMYCIN AND METRONIDAZOLE IN A PATIENT WITH ULCERATIVE COLITIS (UC): A CASE REPORT

FECAL MICROBIOTA TRANSPLANTATION IN RECURRENT NAP1/B1/027 CLOSTRIDIUM DIFFICILE INFECTION (CDI) RESISTANT TO VANCOMYCIN AND METRONIDAZOLE IN A PATIENT WITH ULCERATIVE COLITIS (UC): A CASE REPORT (Abstract): Most of the studies showed that IBD patients inflammatory bowel diseases (IBD) with CDI have more of the whole range of short- and long-term worst outcomes than those without CDI. Initial infection with the BI/NAP1/027 epidemic clone was found to be a significant risk factor for relapse. However, current literature is suggesting increasingly that for patients with infections that fail to resolve with traditional antibiotic regimens, FMT's average cure rate of > 90%. We report a case of a 40-year-old man, diagnosed with ulcerative colitis (UC) in 2012 who presented in our clinic for 20 watery stools per day with mucus and blood, hypogastric pain, pyrexia and chills. Rectosigmoidoscopy and histopathological examination diagnosed active lesions of ulcerative colitis with *Clostridium difficile* toxins A/B enzyme immunoassays (EIA) testing initially negative. The patient was non-responder at day 10 of intravenous (iv) corticotherapy and received induction therapy with Infliximab 5 mg/kg. EIA testing for *Clostridium difficile* was repeated at day 12 of hospitalization with positive results for toxins A/B, and associated oral therapy with Vancomycin and Metronidazole was initiated without clinical response in day 7, reasons for what intravenously therapy with Tigecycline was started with good response. Patient was discharged after 10 days of Tigecycline, but came back twice for two relapses of *Clostridium difficile* colitis treated successfully with Tigecycline, reasons for what fecal transplantation was performed in Matei Bals Institute, which induced remission of both CDI and UC. **Keywords:** FECAL MICROBIOTA, TRANSPLANTATION, CLOSTRIDIUM DIFFICILE, INFECTION, ULCERATIVE COLITIS.

Most of the studies showed that IBD patients with CDI have more of the whole range of short- and long-term worst outcomes than those without CDI. Patients with ulcerative colitis have more severe outcomes than those with Crohn's disease (1).

Rates and severity of *Clostridium difficile infection* (CDI) in hospitals in North America and Europe have increased since 2000 and correlate with dissemination of an epidemic strain characterized by higher than usual toxin A and B production, the presence of a third toxin, binary toxin, and

high-level resistance to antibiotics. The strain, which is restriction endonuclease analysis group BI, pulse-field gel electrophoresis type NAP1, and polymerase chain reaction ribotype 027, is designated BI/NAP1/027 (2, 3, 4).

CASE PRESENTATION

A 40-year-old man, was admitted in our department in May 2014, for 20 watery stools per day with mucus and blood, hypogastric pain, pyrexia and chills.

His medical history includes chronic hepatitis B infection in treatment with entecavir 0.5 mg per day and UC diagnosed in 2012, in treatment with azathioprine at a dose of 150 mg per day (2,5 mg/kg). He confessed cessation of smoking for one year, previously being a chronic smoker of 20 cigarettes per day.

Should be mentioned in his medical history multiple flares of UC since diagnosis due to low-compliance to medication, also self-discontinuation of azathioprine 2 weeks before hospital admission because of lack of money.

At clinical examination the patient was apyretic, underweight with a BMI of 17,5 kg/m^2 with skin and mucosal pallor, tachycardia and with tenderness in lower abdomen with palpation.

Laboratory tests showed moderate leukocytosis, important increase in C-reactive protein levels and hypochromic microcytic anemia.

Stool test were negative for infections. *Clostridium difficile* toxins A/B enzyme immunoassays (EIA) tested negative.

Rectosigmoidoscopy revealed: absent vascular pattern, edema, erythema, friability of the mucosa and erosions. Continuous lesions on 60 cm explored (fig.1).

Histopathological examination showed: Diffuse chronic mucosal inflammation, cryptitis, regenerating epithelium with erosion and superficial fibrino-leukocytic exudate, HE, 200 x (fig. 2)

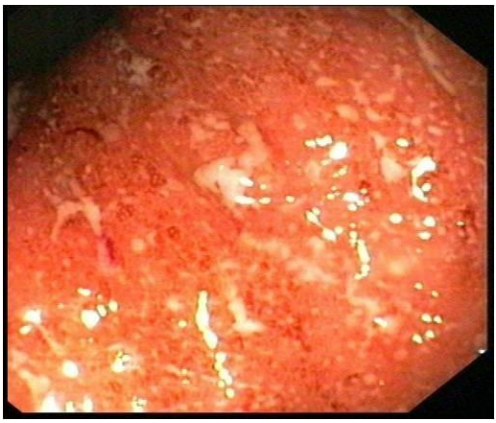

Fig. 1. Rectosigmoidoscopy absent vascular pattern, edema, erythema, friability of the mucosa and erosions.

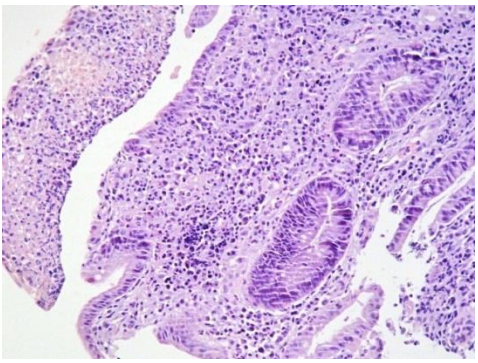

Fig. 2. Histopathological examination diffuse chronic mucosal inflammation, cryptitis, regenerating epithelium with erosion and superficial fibrino-leukocytic exudate, HE, 200x

The severity of UC flare was framed in a Mayo score of 12 points.

The patient received intravenous (iv) corticotherapy with lack of response at day 10.

First induction dose of infliximab 5

mg/kg was administered with the maintenance of oral corticotherapy. EIA testing for *Clostridium difficile* was repeated at day 12 of hospitalization with positive results for toxins A/B.

We decided to stop further administration of infliximab and start tapering corticotherapy until *Clostridium difficile* eradication. We initiated oral Vancomycin 1000 mg per day in association with oral Metronidazole 1500 mg per day and *Saccharomyces boulardii* capsules 500 mg per day. After three days the patient developed digestive intolerance with vomiting and the regimen was changed to i.v. Metronidazole 1,500 mg/day.

At day ten of treatment the patient had a decrease in the number of stools (9 per day, with no blood but with the presence of pus), still with persistent abdominal pain. Blood tests showed no modification regarding inflammatory panel with increased values in serological inflammatory markers, severe hypochromic microcytic anemia that required blood transfusions and severe hypoalbuminemia.

Fecal cytology showed the presence of leukocytes.

Nucleic acid amplification test (NAAT) for *Clostridium difficile* toxin genes was positive for hipervirulent NAP1/B1/027 strain.

Oral vancomycin was continued with increased dosage 2,000 mg per day (500 mg every 6 hours) in association with vancomycin enemas 500 mg four times per day.

After ten days of previous regimen due to lack of response we added tigecycline 50 mg every 12 hours intra-venously for 16 days with clinical response consisted in normalization in the frequency and consistency of stools.

The patient was discharged from hospital with the recommendation to continue vancomycin in a tapering regimen 250 mg four times daily with halving doses weekly until 125 mg every other day for 7 days in association with *Saccharomyces boulardii* capsules 500 mg per day. Oral corticotherapy tapering was continued.

After one month the patient was readmitted to the hospital for the recurrence of watery bloody stools and severe abdominal pain.

We performed EIA retesting for *Clostridium difficile* which was positive for both toxins A and B and fecal cytology which showed the presence of leukocytes.

Patient received a second course of intravenous tigecycline 50 mg every 12 hours with favorable evolution and the normalization of stools at day 7.

At two weeks follow up the patient presented with the second relapse of *Clostridium difficile* colitis and again was treated with tygecicline in association with oral metronidazole, oral vancomycin and *Saccharomices boulardii* capsules with favorable evolution.

After this third recurrence of Clostridium difficile infection patient received fecal microbiota transplantation (FMT) in Matei Bals Institute with a donor from the personal of the Hospital, through a nasogastric tube.

One month after, the patient had a fourth recurrence of *Clostridium difficile* colitis meeting the same pattern as the previous and we performed a second procedure of FMT (changing the donor with one person from the patient's village).

At further follow-ups for a period a 2 years the patient was in clinical remission of inflammatory bowel disease with the normalization of clinical examination, weight

gain and with normal range for serological inflammatory markers, on maintenance therapy with oral 5-ASA 3 g/day.

DISCUSSION

The endoscopic finding of pseudo membranes found in 50% of *Clostridium difficile* infected patients (according to data from last decade) is less common (13%) in IBD patients with CDI (7) and our case had also an endoscopic aspect of ulcerative colitis flare.

A strong pre-test suspicion for CDI (as in our case watery diarrhea, severe hypoalbuminemia, severe anemia, severe acute inflammatory syndrome), empiric therapy for CDI should be considered regardless of the laboratory testing result, as the negative predictive values for CDI are insufficiently high to exclude disease in these patients (8). In our patient the clinical presentation of Clostridium difficile colitis mimics an underlying IBD flare and the first test for toxins in the stool was negative, and that made us to escalate the immunosuppressive therapy that lead to a very severe evolution of this patient.

Toxins A+B EIA testing commonly used as first diagnosis test for *Clostridium difficile* infection has a sensitivity of single sample testing low (72%) and may increase by 10% with second stool testing (84%). Three sample testing increase sensitivity to 86%(8).

Currently, standard recommendations for treatment of mild CDI include metronidazole or vancomycin, with data suggesting that vancomycin is more efficacious than metronidazole in severe CDI (1).

This is the first Romanian report of a case of *Clostridium difficile* colitis with the BI/NAP1/027 strain in a patient with ulcerative colitis, community acquired. Rafila et al report in their study that PCR ribotype 027 was found to be the most dominant type in CDI in Bucharest, accounting for 68% of the Romanian isolates during 2011-2012, 84% healthcare associated and 16% community acquired (9). Now we report resistance of this strain to metronidazole or vancomycin and a good response to tigecycline therapy, which practically saved the life of this patient.

We think that Infliximab worsened the evolution of C difficile infection in our patient, our point of view differs from Seicean A et al (10). FMT was indicated because of repeated relapses of C difficile colitis, according to current data from the literature (5). FMT practically cured both diseases, with the condition of a good quality donor.

ACKNOWLEDGEMENTS

Dr. Camelia Ghita from the Epidemiology Department, Clinic Fundeni Institute, Bucharest for his support in establishing a correct diagnosis and therapy in this case and dr. Catalin Apostolescu from the Infectious Disease Department, "Matei Bals" Institute, Bucharest who performed the fecal microbiota transplantation.

NEWS

SUCCESSFUL DIETARY INTERVENTION IN PATIENTS WITH SYSTEMIC SCLEROSIS AND FRUCTOSE MALABSORPTION

Gastrointestinal involvement is frequent in systemic sclerosis (SSc) and leads to an important decrease in patients' quality of life. A recent study aimed to evaluate the prevalence of fructose malabsorption in 80 patients with systemic sclerosis recruited between 2011 and 2014. The study group was composed of 23 patients with diffuse cutaneous SSc (dcSSc) and 57 patients with limited cutaneous SSc (lcSSc). Gastrointestinal symptom severity was quantified using the Global Symptomatic Score (GSS). A respiratory test was performed according to strict protocols to estimate fructose absorption following the ingestion of 250 ml 10% fructose solution. Fructose malabsorption was shown in 40% of SSc patients with a higher prevalence in patients with lcSSc (78.1% in lcSSc vs 21.9% dcSSc patients). Fructose malabsorption was strongly correlated with higher GSS scores (p=0.000004). However, BMI values did not differ significantly between individuals with or without fructose intolerance. Patients that exhibited fructose malabsorption were placed on a low fermentable oligosaccharides, disaccharides, monosaccharides and polyol diet (low-FODMAP) for a period of 5 weeks. Symptoms like nausea, vomiting, diarrhea, constipation and abdominal pain were reduced significantly (up to 0%) by the low-FODMAP diet. The study emphasizes the importance of personalized dietary interventions in SSc patients. (Marie I. et al. Fructose Malabsorption in Systemic Sclerosis. *Medicine* 09.2015, doi: 10.1097/MD.0000000000001601. 94 : 39 : e1601).

VENOUS ULCER - A NEW THERAPEUTIC APPROACH

R.F. Popa, I. Cazan*, Genoveva Baroi, Simona Cazan, G. Lefter, Cristina Strobescu
University of Medicine and Pharmacy "Grigore T. Popa" - Iaşi

VENOUS ULCER-A NEW THERAPEUTIC APPROACH (Abstract): Trophic leg ulcer is a major health problem affecting approximately 1-2% of the population, the incidence being higher in the elderly (70-80 years). It is a multifactorial condition, but the most common cause is chronic venous insufficiency. This can be attributed to reflux in the saphenous system and calf perforator vein incompetence. These were first described by Linton, the first intervention designed to correct perforator vein incompetence bearing his name. Today Linton's operation has been abandoned due to the large unaesthetic incision and great postoperative pain. Also, ulcer healing time is long (2 months) and recurrence rate is high. Currently a series of minimally invasive procedures are used to close these perforator veins, such as ultrasound-guided sclerotherapy. The advantages of these techniques are less discomfort to the patients, low rate of complications, short hospital stay. **Keywords:** LEG ULCER, PERFORATOR VEINS, SUBFASCIAL ENDOSCOPIC PERFORATOR SURGERY, ULTRASOUND GUIDED SCLEROTHERAPY, MINIMAL INVASIVE.

Trophic leg ulcer (TLU) is a major health problem affecting approximately 1-2% of the population at some point in time, the incidence being higher in the elderly population (70 to 80 years) (1). It is also associated with high financial costs, the treatment usually being of long duration. TLU is associated with reduced quality of life and high morbidity (2). Venous ulcers are known to have the highest rate of recurrence, 25% of cases relapsing within the first year (1). This condition is multifactorial, but the most common cause is venous insufficiency accounting for 70% of all leg ulcers. It was estimated that 4% of patients with chronic venous insufficiency develop venous stasis ulcers (1). Beside greater saphenous vein incompetence it is also associated with the presence of incompetent calf perforators, thus the treatment would be incomplete if it deals only with the greater saphenous vein neglecting the incompetent perforator veins, ulcer recurrence being therefore high (1,3). Not too long ago, the incompetent perforator veins were surgically corrected with the Linton operation (which requires a large unaesthetic incision and causes great postoperative pains) or sub fascial endoscopic perforator vein *s*urgery. Currently, minimally invasive endovascular percutaneous methods are used. As these methods do not require anesthesia or sedation, patients experience little discomfort, the complication rate is low, and a hospital stay short (3).

Venous insufficiency of the great saphenous vein correlates with the number of incompetent perforator veins per leg as

well as the diameter of the perforator veins (4). This implies that the presence of venous reflux through the perforators is an important factor in developing venous reflux in the greater saphenous vein. Chronic venous insufficiency is associated with perforator vein insufficiency in approximately 77% of patients with venous stasis leg ulcers and 57% of patients with trophic changes in the lower extremities. Interruption of the perforator veins with significant reflux (shown by Doppler ultrasound) must be done especially in cases associated with such trophic skin changes as dermatitis, hyperpigmentation, lipodermatosclerosis, and most importantly active stasis ulcers. Patients with recurrent varicose veins have a higher prevalence and a greater number of incompetent perforator veins (5,6).

The perforator veins go through the fascia connecting the superficial and deep venous systems. Most have bicuspid valves (1-3) which assure the one-way flow of blood from the superficial to the deep venous system. This is also favored by the oblique trajectory of the perforator veins.

The first classification of perforator veins was (fig. 1):

- Cockett perforators which connect the greater saphenous vein with the posterior tibial vein;
- Boyd perforators situated immediately under the knee, connecting the greater saphenous vein with the tibial and popliteal veins;
- Bassi perforators between the lesser saphenous veins and peroneus veins;
- Dodd (Hunterian) perforators between the greater saphenous vein and the popliteal and femoral veins.

The International Interdisciplinary Consensus Committee on Venous Anatomical Terminology recommends the classification of perforators into 6 groups depending on the anatomical position in the lower extremities: perforators of the foot, ankle, calf, knee, thigh, gluteus. One of the objectives of this classification is to allow topographic description of the perforator veins without relying on person's names which are quite often historically inaccurate (7).

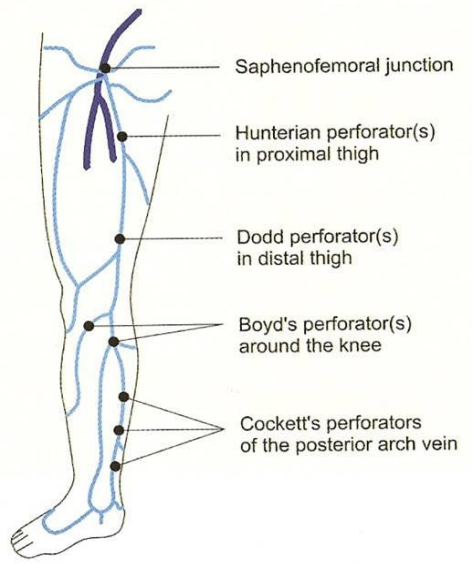

Fig. 1. Perforator veins of the lower leg (7)

The incompetent perforator vein is identified as follows: depression in the muscular fascia, area in which at little digital pressure the reflux can be felt during the Valsalva maneuver or cough. On Doppler ultrasound these perforators have a diameter greater than 4mm and a reflux higher than 0.35 seconds (8).

Precise indications for perforator vein interruption are necessary in clinical practice in order to offer a basis for evaluating treatment outcome. These indications are:

- ulcer healing in extremities with Clinical-Etiology-Anatomy-Pathophysiology (CEAP) class C6;
- prevention of ulcer recurrence in ex-

tremities with classes C5 and C6;

- lowering of severity of chronic venous insufficiency and resolution of symptoms in stages C2 to C5;

- prevention of progression to more advanced stages in C2 to C4 extremities (9).

This first technique to close the perforator veins was the Linton operation (1938) which consists of a longitudinal incision followed by the dissection and subfascial ligation of the perforator veins (10).

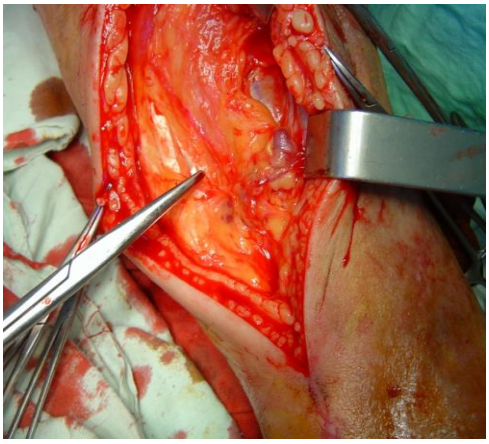

Fig. 2. Linton operation

The second method is sub fascial endoscopic perforator surgery (SEPS). It became the most accepted surgical method for advanced stages of chronic venous insufficiency. The results offered by the North American SEPS Registry show a rate of ulcer healing of 88% at 1 year following the procedure and a higher ulcer recurrence rate in the patients with postthrombotic syndrome compared to those with primary chronic venous insufficiency (11).

The new therapeutic standards is a minimally invasive procedure which does not require anesthesia or sedation (patients are usually old and have a history of other medical illnesses), causes little discomfort to the patients, low complicationrate, and short hospital stay. This standard can be achieved through the ultrasound-guided sclerotherapy of perforator veins.

Sclerotherapy is used for the treatment of perforators with a diameter of 4-7 mm, the ones less than 4 mm in diameter being rarely incontinent and those greater than 7 mm requiring a larger amount of sclerosing substance and thus are at higher risk for complications. Under ultrasound guidance the vein is punctured with a 25 gauge needle, venous blood is aspirated to check needle placement into the vein, injection of 1-2 ml polidocamol foam, needle retraction, compression for a few minutes, and ultrasound control for persistent flow (fig. 3). Postoperatively, elastic compression is instituted for 24-48h followed by 5 days of daytime elastic compression (minimal period).

Post procedural ultrasound examination shows thickened venous wall, change in vein diameter, absent flow, and higher echogenicity. A significant decrease in echogenicity signifies the presence of thrombosis and it is associated with a high risk of thrombus propagation into the deep venous system or recanalization (9,12).

Immediate success rate is >98% and at 6 month > 90% perforators remained closed. Post procedurally, the venous ulcers heal quickly and if they are of great size a skin graft should be used. There is no evidence that ulcer recurrence is caused by the same perforator which underwent recanalization or by a new incompetent venous perforator (13,14) (fig 4).

Complications of ultrasound-guided sclerotherapy: multiple punctures can lead to vasospasm and hematoma which will make the procedure difficult, accidental injection of the substance into the artery, cutaneous necrosis, and anaphylactic shock (13).

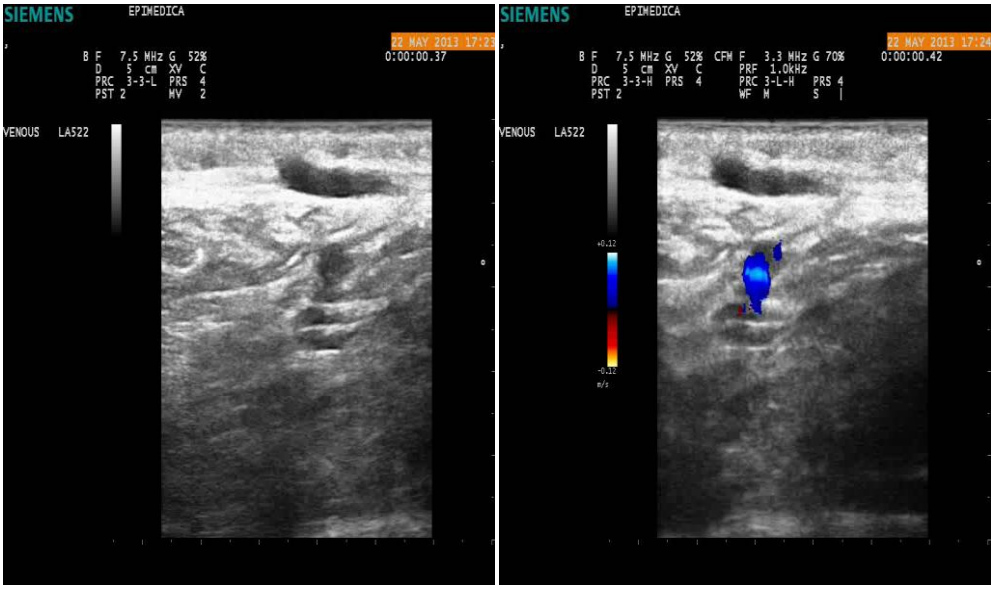

Fig. 3. Sclerozing substance injection into the perforator vein site

Fig. 4. Venous ulcer healing after the ligation of the saphenous-femoral junction = ultrasound-guided sclerotherapy and skin grafting.

CONCLUSIONS

Our experience with patients with stasis ulcer and trophic changes associating chronic venous insufficiency with perforator vein reflux should undergo perforator vein besides classical surgical treatment of venous insufficiency, otherwise ulcer healing time is longer and recurrence rate is

high.

In our clinic approximately 150 patients with venous leg ulcers and incompetent perforator veins were treated by sclerotherapy. The postoperative results showed that ultrasound-guided sclerotherapy of incompetent perforators is a minimally invasive method effective in the treatment of venous ulcers. The immediate favorable results in a high proportion of cases, low rate of complications, accessibility, and the fact that patients can resume their normal activities immediately after the procedure highly recommend it. Ulcer healing time is short and the incidence of leg ulcer recurrence is low.

PROLONGED FEVER WITHOUT OBVIOUS ETIOLOGY FINALLY DIAGNOSED AS HIGH-GRADE SOFT TISSUE SARCOMA

PROLONGED FEVER WITHOUT OBVIOUS ETIOLOGY FINALLY DIAGNOSED AS HIGH-GRADE SOFT TISSUE SARCOMA (Abstract): Sarcomas represent a challenge to clinicians as they are rare and diagnosis is often delayed. Soft tissue sarcomas are relatively uncommon cancers, the incidence is estimated about 1% from all malignant tumors. Due to aggressive biological behavior of pleomorphic undifferentiated sarcoma diagnosis must be made as quickly as possible. MRI is the standard imaging modality for investigating possibly malignant masses. Excisional biopsy appears to be necessary for differentiating soft tissue sarcoma from expanding hematoma. FDG PET scans may be helpful in specific circumstances (as was the situation in our case, because the lesion is composed from two components: an area without precise edges and a necrotic-cystic area). **Keywords:** SOFT TISSUE SARCOMA, FDG PET SCAN, PROLONGED FEVER, EXCISIONAL BIOPSY.

The large majority of soft tissue tumors are benign, with a very high cure rate after surgical excision. Soft tissue sarcoma (STS) incidence is estimated about 1% of malignant tumors, life-threatening being the main problem, the diagnosis and treatment representing a significant challenge due of more than 50 histological subtypes of soft tissue sarcomas which often have specific characteristics in clinical presentation, prognosis and treatment (1).

Undifferentiated high grade sarcomas are usually present in patients aged over 40 years, predominance beings around the age of 60-70 years, rare examples may be encountered in adolescents and young adults. Preponderance it's a little bit higher in men versus women, approximately 1.2:1(2). STS distribution according to the anatomic area as follows: head and neck 8.9%, trunk 17.9%, upper extremities 13.1%, lower extremities 46.4%, retroperitoneum 12.5%, mediastinum 1.3% (3). In the extremities, STS it's presenting most often as a painless lump or swelling, usually 5-10 cm in diameter, located in muscle (4). In order to be able to differentiate between various types of sarcomas and discriminating through the newly diagnosed low-grade and high-grade sarcomas, a high sensitivity it's required and this may be achieved by combining metabolic and morphological information of FDG PET/CT imaging (5). These combined images have been already used for multiple purposes: biopsy guidance, response assessment , grading, and follow up in STS (6).

Among the most often used systems for classification we notice: French grading and the National Cancer Institute grading,

which are based on histologic type and subtype, tumor necrosis, and mitotic activity. Further evolution to metastatic disease is given by histological grading which is also an important prognostic factor (7).

CASE REPORT

A 67 years old Caucasian female, without significant medical history, was admitted with prolonged fever (up to 39°C), chills, sweats, diffuse myalgia, fatigue, persistent inflammatory syndrome, weight loss (10 kg in last 5 months) and a recent appearance of a pain in left thigh without swelling. The medical investigations performed before admission: thorax scanner, bone scintigraphy, abdominal ultrasound and transthoracic cardiac echography were negative. The patient was treated during 15 days with corticosteroids (Medrol 12 mg/d), but without symptomatic improvement.

Clinical examination reveals pain on deep palpation in the left trochanter without local swelling. Vital parameters were normal except the fever.

Laboratory investigations show the following results: CRP 148mg/L, hemoglobin 10,2g/dL, ferritinemia 840,4µg/L(normal value between 30 to 400), serum iron 16µg/dL, hypoalbuminemia 20,9g/L. Bacteriological analyzes of urine and blood were negative.

Due to the fact that the patient began to invoke a pain in left thigh we chose to do some investigations to discover the etiology. A pelvis and femur radiography reveals no bone lesions. A bone scintigraphy shows on the precocious images an intake at the soft tissue of the left thigh. We continued investigations with a hip ultrasound which revealed a heterogeneous formation of 112 mm on 40mm which occurs vascularized. We followed with an MRI exams which detected a lesion of 10 cm containing two components: a fleshy area without precise edges and a necrotic-cystic area, suspicious of malignancy (rhabdomyosarcoma), as illustrated in the following two figures:

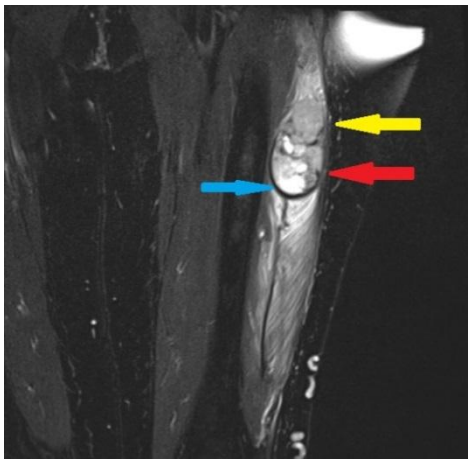

Fig. 1. MRI of the thigh: coronal cut, T2-weighted. The lesion at the vastus lateralis muscle occupying a major part of this muscle, that seems not to cross the vast intermediate aponeurosis, showing a double signal: the cranial part appears fleshy (yellow arrow) and caudal part appears necrotic-cystic (red arrow) well delimited by a fibrous membrane (blue arrow).

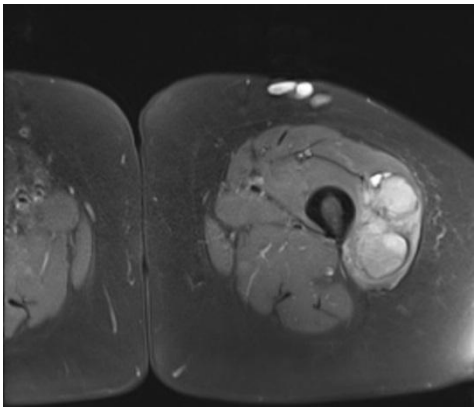

Fig. 2. MRI of the thigh: axial cut, T2-weighted. The lesion in the vastus lateralis muscle occupying a major part of this muscle.

We have continued the investigations with a FDG PET scan which revealed us a voluminous lesion very hypermetabolic. We proceeded to the surgical excision of the mass which led us to the diagnosis of soft tissue sarcoma.

DISCUSSION

Unexplained prolonged fever is characterized by a higher temperature than 38,3°C(101°F) lasting more than 3 weeks for no apparent reason after clinical examination and routine tests.

The main causes of prolonged fever (except patients with a known HIV positive serology) are: infections (20 to 35% of cases), malignancies (10 to 15% of cases), autoimmune conditions (20 to 30% of cases) and miscellaneous (5 to 15% of cases) (8). In rare cases, soft tissue sarcoma can cause general symptoms such as: fever, chills, sweats, weight loss, fatigue. Soft tissue sarcoma in its early stages may grow without any signs or symptoms, pain or soreness appear when it presses against nearby nerves and muscles.

The first imaging test is a X-ray, followed by an MRI which is the most helpful test to image soft tissue tumors as it provides very important information about the mass such as the size, location, and proximity to neurovascular structures but the diagnosis of a tumor cannot be made by MRI alone. MRI cannot be done to patients with metal implants or pacemakers, in those cases a CT scan may be an option.

Rhabdomyosarcoma is part of tumors of the musculoskeletal tissue for which the performing of a 18F-fluorodeoxyglucose (FDG) PET-CT is indicated in order to stage the high-grade sarcomas (9). Considering the suspicion of rhabdomyosarcoma and that the lesion has several components, to avoid the risk of false negative result at biopsy we opted to continue investigations with a FDG PET scan due its direct relationship to tissue metabolism. The highest FDG uptake areas in a tumor reflect the most biologically aggressive areas with the probability of malignant behavior.

Below we present PETAC axial and axial CT images which have been fused to obtain a third image which shows a voluminous lesion very hypermetabolic.

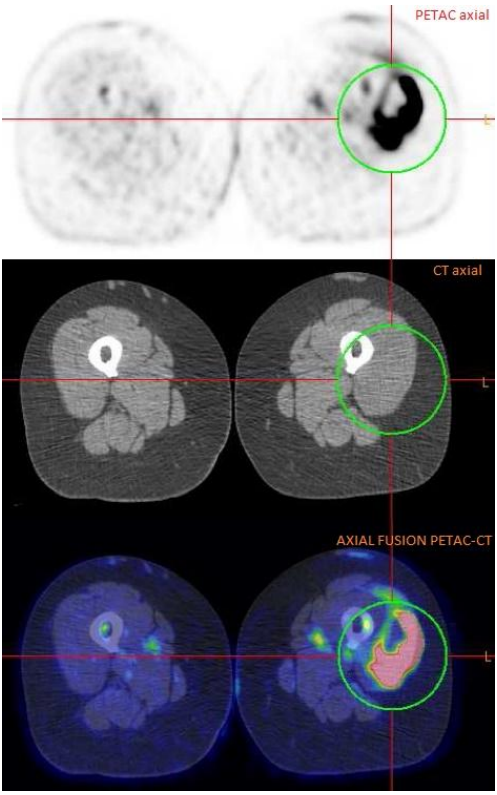

Fig. 3. Fusion between Positron Emission Tomography with Carbon-11 Acetate axial and CT axial images.

The standard uptake value(SUV) used in Flourodeoxyglucose (FDG) imaging, has the capability in helping to distinguish between benign and malignant lesions, high SUV uptake may predict for an aggressive

histology. Because the lesion was intense hypermetabolic (SUVmax=49,6) we decided a total excision of the mass.

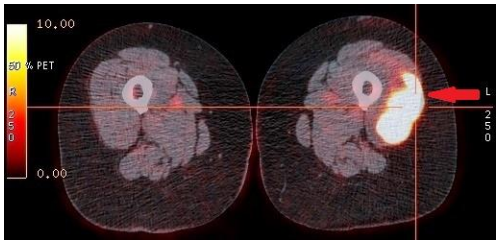

Fig. 4. Fused axial PET/CT images showed tracer uptake in a bulky soft-tissue mass in the left vastus lateralis muscle as indicated by red arrow

In case of mass suspicious of malignancy, the FDG PET image used in conjunction with other imaging can guide the surgeon to the most appropriate area to get biopsy tissue for diagnosis because the most biologically aggressive areas of a tumor have the highest FDG uptake (10).

Only the biopsy can provide a specific histological diagnosis of pleomorphic sarcoma which cannot be obtained by radiologic imaging. There are three procedures to obtain biopsy: fine needle aspiration (FNA) is not recommended as a primary diagnostic modality, core needle biopsy but several cores should be taken to maximize diagnostic yield and excisional biopsy.

After analyzing of surgical fragments, the anatomopathological result concludes the following diagnostic: Soft Tissue Sarcoma undifferentiated High-Grade 3 in the classification FNCLCC (Federation Nationale des Centres de Lutte le Cancer).

When the diagnosis of sarcoma is made, it is important to determine if a tumor is isolated (localized) or has spread (metastatic) by way of PET scan, which nowadays has become a routine exam in the extension evaluation of STS. Sarcomas can develop distant metastases and the most common site is the lung with the observation that if a pulmonary nodule is discovered after the patient has been diagnosed with a sarcoma, this one may be a metastasis of sarcoma. Rarely metastases may occur in the skin, soft tissues, liver, and lymph nodes (11).

Once the diagnosis of Soft Tissue Sarcoma has been confirmed, an individual treatment plan is made for each patient. Sarcoma treatment requires a multimodality approach and hence a team of physicians will participate in a patient's care. There are essentially three main types of treatment: surgery, radiation, chemotherapy.

Adjuvant chemotherapy is among the treatments that can reduce the risk of developing subsequent systemic metastasis in addition to achieving a good local control in case of high grade sarcomas, greater than 5cm (12).

In our case, after surgical excision of the tumor (with healthy margins of resection) were not found metastases in tests performed. Due of large size of the tumor (10 centimeters) and because there were no metastases found corroborated with a good health condition of the patient, we had considered appropriate to administrate an adjuvant chemotherapy by Adriamycin 3 sessions of intravenous continuous infusion over 3 days every 3 weeks followed by a complement of radiotherapy.

CONCLUSIONS

In prolonged fever of unknown origin we can expect sometimes an infrequent diagnosis, so the presumptive diagnosis should not remain obtuse, but must keep a wide vision to avoid missing the rare diagnosis and particularly aggressive as in our case. Diagnostic steps must be well structured in order to reach the diagnostic as quickly as possible to discover the disease in its earliest stages

to improve the survival prognosis.

While some imaging scans such as CT and MRI isolate organic anatomic changes in the body, PET is capable of detecting areas of molecular biology detail (even prior to anatomic change).

The high diagnostic accuracy of FDG-PET and PET/CT has been well documented for several neoplasms, with a consequent rapid increase in the utilization and acceptance of PET imaging in the clinical setting.

INFLAMMATORY ABDOMINAL AORTIC ANEURYSM - A FORM OF CHRONIC PERIAORTITIS (Abstract). Chronic periaortitis represents a unique pathogenic concept for three entities: Inflammatory Abdominal Aortic Aneurysm, Idiopathic Retroperitoneal Fibrosis and Perianeurysmal Retroperitoneal Fibrosis. The fundamental meaning of an inflammatory reaction to advanced atherosclerosis has been developed on the bottom of clinical and histological features. The triad of abdominal pain, weight loss and elevated inflammatory markers: erythrocyte sedimentation rate /C-reactive protein in patients with abdominal aortic aneurysms revealed on contrast-enhanced computer tomography is highly suggestive for inflammatory aneurysm. We report a case of a heavy-smoker adult male presented with suddenly abdominal symptoms suggestive for mesenteric ischemia which have proved to be due to inflammatory abdominal aortic aneurysm. The most favorable management of patients with inflammatory aneurysm is ambiguous. Surgical approach seems reasonable even supposing inflammatory aneurysm emerges less likely to rupture than the atherosclerotic variant. Corticosteroids are used in inoperable inflammatory aneurysm, even if is well known that this treatment does not change the long-term outcome of the disease. Surgical-open or Endovascular Repair of the aneurysm is the elective treatment. **Key words:** INFLAMMATORY ABDOMINAL AORTIC ANEURYSM, CHRONIC PERIAORTITIS, RETROPERITONEAL FIBROSIS.

Inflammatory abdominal aortic aneurysm (IAA) represents 10 % of all cases of abdominal aortic aneurysm (1) and is a form of chronic periaortitis (CP) which includes idiopathic retroperitoneal fibrosis and perianeurysmal retroperitoneal fibrosis (2, 3). Unlike atherosclerotic aortic aneurysm, the inflammatory type is characterized by remarkable thickening of the aneurysm wall and fibrosis of the adjacent retroperitoneum (4). The classical presentation consists in the triad of abdominal /back pain weight loss and raised inflammatory markers (2, 5, 6). It is important to recognize inflammatory abdominal aortic aneurysm in order to prevent the severe compli-

cations and the potentially fatal course (2, 6). Contrast-enhanced computed tomography and magnetic resonance imaging (MRI) is a reliable diagnostic modality (7, 8, 9). Knowing the features of inflammatory abdominal aortic aneurysm would allow doctors to distinguish it from atherosclerotic aneurysm and to treat it with the suitable combination of surgical and medical therapies (6, 10).

CASE REPORT

A 61–year-old man, presented with a short history of one week of recurrent diffuse abdominal pain, nausea and vomiting. In the last 24 hours the symptoms got worsened, the abdominal pain increased and localized in the left lower quadrant and low-grade fever appeared. The patient is a heavy smoker, overweight, known with dyslipidemia and has a family history of myocardial infarction, and stroke. In the last two months the patient have had a dull intermittent low back pain which worsen at night and weight loss of 3 kg. He denied intestinal transit alteration or presence of blood in stools.

Clinical examination in the emergency room showed an obese patient with bilateral xanthelasma, abdominal distension, and important pain on palpation on left iliac fossa with no rebound tenderness accompanied by discomfort with palpation in the whole left lower quadrant. Blood pressure 180/110mmHg, heart rate 89/min with extrasystoles.

Investigations showed raised C-reactive protein (CRP) 33 mg/dl and erythrocyte sedimentation rate (ESR) 65 mm/h, mild leukocytosis 12200/mm^3, lactate dehydrogenase (LDH) and creatine kinase MB (CK-MB) slightly increased, low-density lipoprotein cholesterol (LDL-cholesterol) 150 mg/dl, urinalysis were in normal range. Plain abdominal x-ray showed few hydroaeric levels without pneumoperitoneum; abdominal ultrasound revealed aortic dilatation suggestive of abdominal aneurysmal aortic appearance with 40 mm diameter. Chest X-ray was normal. Abdominal computed tomography revealed the presence of a 5 cm aneurysm of the infrarenal abdominal aorta on a length of 7 cm and aneurismal dilatation of both common iliac arteries and also, a soft-tissue density mass enveloping the aorta from the renal arteries down to the aortic bifurcation, that caused left mild hydronephrosis and dilatation of the ipsilateral ureter; the left kidney appeared enlarged, with important densification of perirenal fat extended up to the ureter (fig. 1).

Fig. 1. Abdominal computed tomography

These appearances were consistent with inflammatory abdominal aortic aneurysm, in agreement with cardiologist and vascular surgeon, we decided to perform an angiography which confirmed aneurismal aortic dilatation, normal mesenteric and renal arteries. Additional investigation showed atherosclerotic lesions in the carotid artery, mitral regurgitation and aortic valve stenosis. Serologic testing for autoimmune diseases was negative.

During hospitalization the clinical picture worsened with the appearance of signs suggestive for mesenteric ischemia: intense abdominal distension with ileus, important abdominal pain with vomiting and peritoneal irritation, hemodynamic instability. The medical team (composed of Internal Medicine Specialist and Vascular Surgeon) consultation considered appropriate the surgical treatment for the inflammatory abdominal aortic aneurysm. Transperitoneal standard median open laparotomy was performed, the aneurysmal segment was replaced with an appropriately sized Dacron tube graft and an aorto-bifemoral bypass operation was performed by using another Dacron tube graft. The retroperitoneal fibrosis involved the ureters therefore ureteral dissection was necessary. Intraoperative diagnosis of inflammatory aneurysm was based on the characteristic appearance of an aorta encased in a thick white fibrotic tissue. Specimens were obtained and were sent to the laboratory for histological examination.

The main finding was fibrosis of the adventitia with dense chronic inflammatory infiltrates with lymphoid follicle formation, presence of lymphocyte and other plasma cell proliferation.

As a result of the extensive retroperitoneal fibrosis technical difficulties with increasing bleeding appeared, thus patient had to be transfused in the postoperative period. Postoperative outcome has been favorable.

The first control visit was performed at one month after the operation. Patient underwent clinical examination by vascular surgeons and computer tomography examination at 6 months after the operation and annually thereafter.

One-year follow-up of the outcome contrast-enhanced abdominal computer tomography reveals functional aortic bifemoural prosthesis; mild delay in opacification of both iliac arteries which appear dilated and tortuous. Periaortitis fibrosis tissular mass is diminished compared to previous examination. The kidneys have normal dimensions with regular excretion; there is no hydronephrosis (fig. 2).

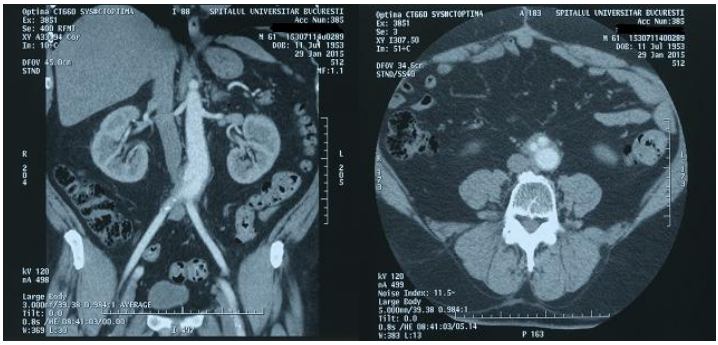

Fig. 2. Abdominal computed tomography at one year follow-up

DISSCUSIONS

Dr. James reported a case of inflammatory abdominal aortic aneurysm in 1935 for the first time. However, barely in 1972 Dr. Walker described histopathological features of inflammatory abdominal aortic aneurysm and formulated a definition in the British Journal of Surgery (4, 11).

Chronic periaortitis represents a rare condition (0, 2 -0, 5/100000/ year) that affect middle - aged/elderly men (12). It includes three diseases that have clinical and pathological related features, and thus being various manifestations of the same disease: inflammatory abdominal aortic aneurysm, idiopathic retroperitoneal fibrosis and perianeurysmal retroperitoneal fibrosis (2, 3, 4). Male sex and smoking are the main risk factors for inflammatory abdominal aortic aneurysm (13). Chronic periaortitis is defined by atherosclerosis of the abdominal aorta, medial thinning, periadventitial inflammation and fibrotic reaction enclosing the abdominal aorta correlated with the retroperitoneal inflammatory process (8). Inflammation and autoimmunity have been discussed as the main pathogenic process leading to periaortitis (2, 14, 15). Admitting the pathogenesis of chronic periaortitis appears to associate an immune response localized to a vessel wall, the etiology of the inflammatory reaction is still unknown (4). Inflammatory abdominal aortic aneurysm is not at all correlated with inflammation of other arteries (4, 8).

In the absence of any autoimmune conditions, the pathogenesis of our case of inflammatory abdominal aortic aneurysm could be the result of a local inflammatory reaction to progressive atherosclerosis process, as Mitchinson's concept proposed about pathogenesis of chronic periaortitis (8). Histological findings include chronic inflammatory infiltrates, comprised B-lymphocytes, even T- lymphocytes and plasma cells in the adventitia distinct to those of atheroma itself (14, 16).

In contrast with non- inflammatory abdominal aortic aneurysm, patients with inflammatory abdominal aortic aneurysm become symptomatic more frequently. The onset of inflammatory abdominal aortic aneurysm is in most cases of nonspecific nature (17). The clinical picture is dominated by abdominal pain, connected to the retroperitoneal mass, which represents the most frequent symptom accompanied by one of these unspecific manifestations of a systemic disease: weight loss, low-grade fever, fatigue, anorexia, vomiting (12). Back or flank pain and colicky pain are suggestive of ureter entrapping (12, 15, 17). Ureteral obstruction is cause of unilateral or worse, bilateral hydronephrosis that leads to renal failure (12, 17).

Diagnosis is made by clinical picture and the imagistic investigations along with nonspecific serologic features. Atheromatous determinations in other territory, cerebral, carotid arteries, ischemic heart disease, complete the clinical picture of inflammatory abdominal aortic aneurysm (12). Inflammation markers, C-reactive protein and erythrocyte sedimentation rate, are invariably raised together with mild normocytic, normochromic anemia and abnormal renal function markers (12, 17).

Contrast-enhanced computed tomography and magnetic resonance imaging are especially important not only for positive diagnosis but for differential diagnosis of a clinical picture centered by abdominal pain and weight loss (5, 18). Computer tomography is the most reliable diagnosis procedure, hence computer tomography images has to be checked cautiously before surgery

decision to recognize evidence like mantle sign, characteristic inflammatory abdominal aortic aneurysm (3, 5, 17). Retroperitoneal fibrosis may also occur secondary to oncologic diseases such as lymphoma, sarcoma or metastasis and not least related with some drugs - for instance methysergide, methyldopa, beta-blockers (12, 15, 19). Therefore, obtaining biopsy specimen of the fibrotic tissue (intraoperative) is mandatory (17).

CONCLUSIONS

The most favorable management of patients with inflammatory aneurysm is ambiguous. Medical treatment of inflammatory abdominal aortic aneurysm exclusively with corticosteroids is controversial (20, 21). Even if some authors reported initial regression of inflammation, recurrence after stopping steroids has been observed. Corticosteroids are used in inoperable inflammatory aneurysm, even though is well known this treatment do not alter the long-term outcome of the disease (22). Surgical approach seems reasonable even supposing inflammatory aneurysm emerges less likely to rupture than atherosclerotic variant (8) and, in comparison with non-inflammatory aneurysms, inflammatory abdominal aortic aneurysm is related to a four-times higher perioperative morbidity and mortality rate (17). Surgical-open or Endovascular Repair of the aneurysm is the elective treatment particularly when the diameter of the aneurysm exceeds 5 cm (8, 23).

BIOFILM-INHIBITORY COMPOUNDS AGAINST *PSEUDOMONAS AERUGINOSA* FROM BURDOCK LEAF

In a study by Lou Z *et al,* basic anti-biofilm profile data for the compounds in burdock leaf were analyzed and a convenient method for fast screening of anti-biofilm compounds from natural plants was provided. According to this study, 34% ethanol elution fraction of burdock leaf could completely inhibit biofilm formation of *Pseudomonas aeruginosa* at 1 mg·mL(-1). Ultra-performance liquid chromatography-mass spectrometry (UPLC-MS) was used to determine the chemical composition of burdock leaf fraction and to obtain the metabolic fingerprints of burdock leaf fractions before and after inhibiting *P. aeruginosa* biofilm. The analysis identified 11 active compounds: chlorogenic acid, caffeic acid, p-coumaric acid, quercetin, ursolic acid, rutin, cynarin, luteolin, crocin, benzoic acid, and Tenacissoside I. Partial least squares discriminant analysis (PLS-DA) of the metabolic fingerprints showed that, among 81 compounds that were screened as potential anti-biofilm ingredients, rutin, ursolic acid, caffeic acid, p-coumaric acid and quercetin are the main anti-biofilm compounds in burdock leaf (Lou Z, Tang Y, Song X, Wang H. Metabolomics-Based Screening of Biofilm-Inhibitory Compounds against Pseudomonas aeruginosa from Burdock Leaf. *Molecules*. 2015;20(9):16266-77. doi: 10.3390/molecules200916266).

DESOGESTREL IN THE PREOPERATIVE TREATMENT OF ENDOMETRIOTIC CYSTS (Abstract): Endometriosis is an estrogen dependent disease characterized by the presence of endometrial tissue outside the uterus. It affects women of reproductive age and is associated with infertility and pelvic pain, with impact on their mental, physical and social well-being. **Aim:** To evaluate the effects of continuous desogestrel treatment on cyst size and the risk of intraoperatively bleeding. **Material and methods:** Our study included two hundred fifty-five patients with infertility and endometriotic cysts operated at the Iasi "Cuza Voda" University Hospital in the interval 2006-2014. One hundred fifty-five patients received 6-month preoperative treatment with 75 micrograms of desogestrel daily. The patients were monitored every three months by vaginal ultrasound associated with Doppler for assessing the cysts size,homogeneity, shape, vascularization, position relative to the uterus and the contralateral ovary, presence of sludge and horizontal levels. **Results:**There was asignificant decrease in cyst diameter and vascularization in most cases with sludge and low echogenicity. Intraoperatively we noticed less bleeding during cyst dissection and a better cleavage plan between the cyst capsule and the normal ovarian tissue. **Conclusions:** Treatment with desogestrel for at least 6 months preoperatively has a shrinking effect on the endometriotic cyst, reduces intraoperative bleeding and improves the dissection and operative conditions. **Keywords:** ENDOMETRIOSIS, INFERTILITY, DESOGESTREL, PELVIC PAIN.

Endometriosis is an estrogen-dependent inflammatory disease defined by the growth of endometrial stroma and glands outside of the uterus, especially on the ovaries and in the peritoneum. Affected women often present with chronic pelvic pain, dysmenorrhea, dyspareunia and infertility (1, 2).

The prevalence of endometriosis increases dramatically to as high as 25% to 50% in women with infertility, and 30% to 50% of women with endometriosis are infertile (3).

It is often cited that retrograde menstruation is the cause of this condition; however retrograde menstruation occurs in nearly all women, yet not all women are afflicted with this condition. Therefore, it has been suggested that women with endometriosis are likely to have underlying molecular abnormalities that allow the continued growth of this endometrial tissue outside the uterus

and that ectopic implantation is possible as a consequence of altered immunity or preexisting peritoneal lesions (4,5).

Ovarian endometriotic cysts are usually detected ultrasonographically but peritoneal lesions and small ovarian cysts are more difficult to detect, so laparoscopy and histopathological diagnosis remain the gold standard. Endometriomas are particularly difficult to excise as the cyst wall is very adherent and well vascularized, thus surgery may reduce the ovarian reserve. The surgical treatment of endometriosis is effective in the short-term, but if the patient does not get pregnant very soon after surgery, it is most probably because endometriosis has relapsed. Recurrence rates after surgical intervention can be decreased with the use of menstrual suppression, such as hormonal contraceptives (6).

Hormone therapy is frequently effective in reducing or even eliminating endometriosis-related pain. The success of various hormonal therapies depends on the location and type of the endometriotic lesions. Superficial peritoneal and ovarian implants seem to respond better to hormone therapy than deep ovarian, peritoneal or lesions within organs. Moreover, hormone treatment has no effect on adhesion of endometriotic cells and cannot improve fertility. Nonetheless, a number of hormonal agents remain the mainstay of endometriosis therapy (7,8).

Progesterone is a potent antagonist of estrogen-induced proliferation in the endometrium and may play a pivotal role in the pathogenesis of endometriosis (9).

Desogestrel is a progestogenic 19-nortestoterone derivative, which is widely used for oral contraception both combined with ethinyl estradiol and alone in progestin-only pills (10).

Our primary goal was to assess the results of treatment with desogestrel regarding improvement of clinical symptoms, ultrasonographic findings and intraoperative bleeding, adhesions and ease of cyst dissection.

MATERIAL AND METHODS

Our study included two hundred fifty-five patients with infertility and endometriotic cysts (diameter less than 20 mm) operated laparoscopically at the Iasi "Cuza Voda" University Hospital Iasi between the years 2006-2014. One hundred fifty-five patients (60.78%) - group A, received a 6-month preoperative treatment with 75 micrograms of desogestrel per day and one hundred patients (39.22%) – group B, received preoperative placebo treatment.

Women with body mass index > 30, neoplasias, autoimmune diseases, diabetes mellitus, infectious diseases, pregnant, under anti-inflammatory or hormonal treatment were excluded from the study.

A written informed consent was obtained from all patients enrolled in the study. The consent form was approved by the Medical Ethics Committee of the Iasi „Grigore T. Popa" University of Medicine and Pharmacy.

The patients were monitored monthly both clinically and ultrasonographically by evaluating the cyst size, homogeneity, shape, vascularization, position relative to the uterus and contralateral ovary, presence of sludge and horizontal levels. All patients were examined by vaginal ultrasound associated with Doppler at the moment of diagnosis and then every 3 months.

In all cases the diagnosis was confirmed postoperatively by histological examination, which demonstrated the presence of histopathologic features similar to endometrium, namely endometrial stroma, endo-

metrial epithelium, glands that respond to hormonal stimuli and hemosiderin deposits.

Age of the patients ranged from 20 to 49 years (mean age 32 years), all of them still menstruating.

The parameters followed intraoperatively were the ease of dissection, amount of bleeding, possibility of conservative treatment, extension of adhesions, and disease staging.

Postoperatively the patients were reevaluated three months later by clinical examination and vaginal ultrasound.

RESULTS AND DISCUSSION

In group A patients (on desogestrel treatment) we found a significant decrease in cyst diameter and vascularization associated with sludge and decrease in echogenicity (tab. I).

TABLE I

Preoperative ultrasonographic changes

	Group A	Group B
Cyst diameter	↓	↑/-
Vascularization	↓↓	↑/-
Sludge and hyperechogenicity	↓↓	↑/-

During the follow-up we noticed in the patients treated desorgestrel (group A) an improvement in clinical symptoms with impact on their mental, physical and social well-being.

In the same group A patients we noticed intraoperatively less bleeding during cyst dissection and a better cleavage plan between the cyst capsule and the normal ovarian tissue (tab. II).

Desorgestrel was well tolerated and no patient had to stop the administration because of side effects. Eighty women became amenorrheic, 58 had irregular vaginal bleeding and 17 women had regular periods. The bleeding amount was described as much lower than a normal period. Fifty-one patients complained of weight gain, the maximum being 5 kg. Twenty-eight patients complained of vaginal dryness and sexual discomfort. Fifty-five patients had decreased libido (fig.1).

TABLE II

Surgical parameters

	Group A	Group B
Easy dissection and capsule cleavage	+++	+/-
Heavy bleeding	+/-	+++
Thick adhesions	+	+++
Operative time	+	++

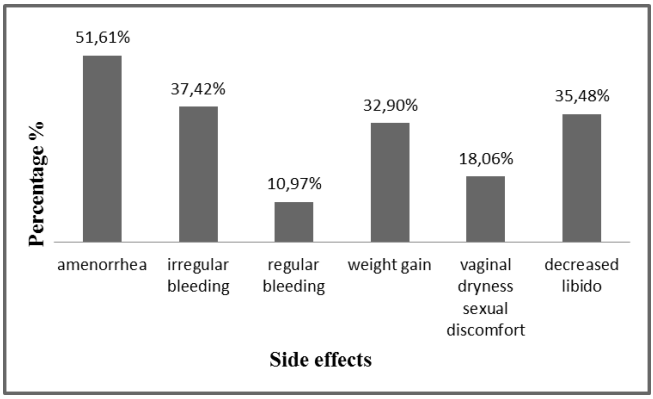

Fig.1. Side effects of Desogestrel treatment

Endometriosis is a major public health problem, due to the number of cases that continues to increase and the risk of consecutive ovarian and endometrial tumors (10% of endometrioid carcinomas of the ovary being associated with uterine endometrioid carcinomas), fact that motivates many researches focused on the mechanisms of endometriosis development and progression (3). Although endometriosis is considered a chronic benign condition, it can present invasive characters, inducing severe symptoms (13).

The study of endometriosis is not fortuitous since this gynecologic disease has an increased incidence, accounting for 2% of the general population, and is the third cause of gynecological checkup for infertility, chronic pelvic pain, dyspareunia and dysmenorrhea. Endometriosis affects 7-15% of women of childbearing age, accounting for 25-30% of cases of sterility, with important social impact (3).

In endometriosis research there are numerous scientific data, with big names in the scientific world who say the same things about its incidence, mechanism of production and social repercussions.

Laparoscopic intervention is the "gold standard" approach in the treatment of endometriosis, and the results may be enhanced with an appropriate technique and reasonable adjuvant therapies (14).

Of the adjuvant therapies for endometriosis, desogestrel may be one of them.

This study showed that treatment with desogestrel improves the operative conditions mainly by decreasing the bleeding and increasing the laxity of the connective tissue between the cyst capsule and the normal ovarian tissue.

However its side effects, such as amenorrhea, irregular bleeding, weight gain and decreased libido as well as its contraceptive action might reduce patient compliance to this treatment.

CONCLUSIONS

In our study, progestative treatment improved the operative conditions and decreased the recurrence risks of ovarian endometriotic cysts.

Treatment with desogestrel for at least 6 months preoperatively has a shrinking effect on the endometriotic cyst, decreases intraoperative bleeding and makes dissection and surgery easier.

In progress researches will demonstrate the action of preoperative treatment with desogestrel on the factors involved in the progression of endometriotic lesions.

NEWS

TEA DRINKING AND TUBERCULOSIS

Numerous studies showed that tea drinking helps to prevent obesity, cardiovascular diseases, autoimmune diseases, neurodegenerative diseases and tumors. Chinese researchers discovered the negative association between tea drinking and tuberculosis (TB). Tea leaves contain epigallocatechin-3-gallate, a flavonoid which inhibit the bacterial growth and the bacillus survival in macrophages. The increasing tea consumption is associated with a decreased risk of TB. Subjects who consumed 151-300 g tea / month had a lower risk to develop TB than those with a lower intake of tea. The green tea led to the most evident protection against TB, compared to oolong and black tea. Future studies are needed to determine whether drinking tea can be used in the prevention and control of TB (Mengshi Chen; Jing Deng; Wufei Li; Dan Lin; Congxu Su; Mian Wang; Xun Li; Benjamin Kwaku Abuaku; Hongzhuan Tan; Shi Wu Wen. Impact of tea drinking upon tuberculosis: a neglected issue. *BMC Public Health* 2015;15(515)).

LIVER METASTASIS OF A GASTROINTESTINAL STROMAL TUMOR OF LARGE BOWEL: CASE REPORT (Abstract): Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal malignancies of the digestive tract. We present the case of a 61-year-old male patient liver metastasis of a GIST with primary location at the level of sigmoid colon. Like in the majority of cases, the symptomatology in this patient has long been faint and when it became manifest, it was nonspecific. Imagery wise, the computer tomography (CT) scan was the most efficient, showing the origin of the tumor from large bowel, its dimensions, as well as the relations with the other abdominal viscera and the liver metastasis. Surgery in this patient was en-bloc, according to the principles of GIST and for the metastasis he followed treatment with Imatinib. The histological aspect is characterized by a proliferation of spindle cells positive for CD117 and CD34. Despite complete microscopic resection, the exhibit of liver metastasis remains an important relapse factor. **Keywords:** GASTROINTESTINAL STROMAL TUMOR, LARGE BOWEL, LIVER METASTASIS.

Initially believed to arise from smooth muscle cells, it is now known that gastrointestinal stromal tumors (GISTs) are malignancies that arise from the interstitial cells of Cajal, which are pacemaker cells found in the bowel wall (1).

They are defined pathologically as c-Kit-positive mesenchymal spindle cell or epithelioid neoplasms (2). The most common location of GISTs are stomach (60-70%), followed by the small intestine (20-30%), the rectum (5%) and the esophagus (<5%). Patients with GISTs are 70% symptomatic but mostly nonspecific, while 20% are asymptomatic and the tumors are detected incidentally and a part of cases are detected during autopsy. The most common symptoms of GISTs are nausea, vomiting, abdominal discomfort, bleeding from the gastrointestinal tract and weight loss. The most common

metastatic sites are the liver and peritoneum, whereas GISTs are rarely found to metastasize intracranially or to the lymph nodes, lungs or subcutneous tissue (3, 4, 5). That being said, surgical resection is still the most important component in the treatment of resectable non-metastatic GISTs (6). Also, with the aforementioned advances made in the medical treatment of these tumors, there is the possibility of a future broadening of surgical indications to include patients with metastatic disease, but this currently remains investigational (7). Imatinib mesylate, a tyrosine kinase inhibitor, shows high clinical efficacy in advanced GIST (8, 9) and is now the standard treatment for unresectable and metastatic GISTs (10). The response to imatinib is known to depend on the mutation sites of the c-kit gene or the platelet-derived growth factor receptor alpha gene (11). The present article describes one case of liver metastasis in patient with GISTs of large bowel and reviews the relevant literature.

CASE REPORT

We report the case of a 61-year-old male patient. He presents pain in lower left abdomen what subside after defecation, accompanied by a quick sensation of fullness after meals and pollakiuria. These symptoms appeared in last three months, worsening progressively. Physical examination reveals lipomas in the abdominal region, chest, neck and limbs, painful left hypogastric region, a palpable tumor in the left iliac fossa, fixed to the deep anatomic plans, with a diameter of 15 cm and hepatomegaly.

We didn't found any pathological laboratory tests except LDL-cholesterol 300 mg/dl and triglycerides 180mg/dl.

The patient's medical history includes lipomatosis, dyslipidemia, and heart attack in 2005 with percutaneous transluminal angioplasty with stent, hepatic steatosis, and liver hemangiomas.

A week before admission in our hospital he was diagnosed in another medical service with left kidney stones and liver hemangiomas.

In our service he made an abdominal ultrasonography which shows a tumor with a maximum diameter of 15 cm, heterogeneous, with interior transonic images, which occupies the hypogastrium and left iliac fossa without being able to specify the origin (fig. 1) .

The right hepatic lobe (segment V, VI, VIII) contains tree lesions hypoechoic, with peripheral halo, size 25mm, 35mm, 54mm and multiple lesions hyperechoic (segment III, IV, VII, VIII), well defined, size 5 to 18 mm without Doppler signal (fig. 2).

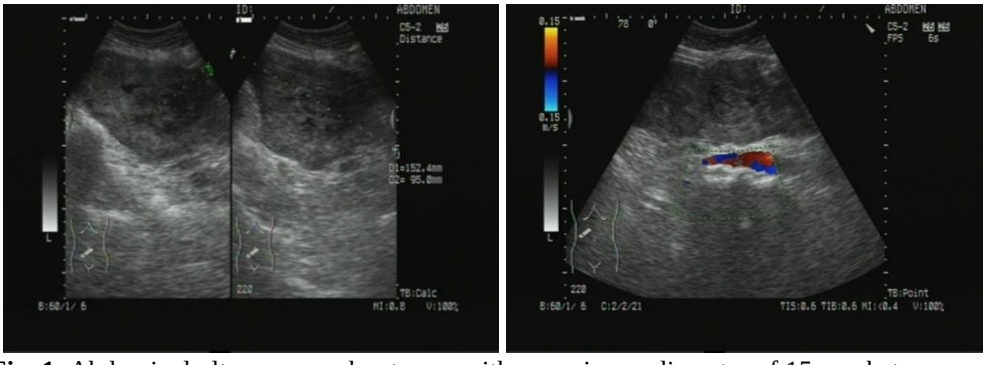

Fig. 1. Abdominal ultrasonography: tumor with a maximum diameter of 15 cm, heterogeneous, with interior transonic images, which occupies the hypogastrium and left iliac fossa.

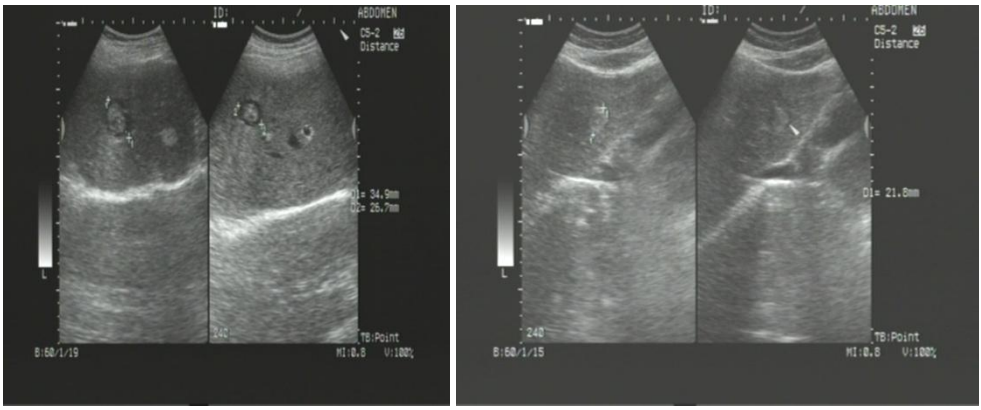

Fig. 2. Abdominal ultrasonography**:** Liver metastasis and hemangiomas

Colonoscopy exam revels between 40 and 45 cm from the anus segmental venous dilatation with no other pathological lesions (fig. 3).

Computerized tomography shows a heterogeneous tumor size117/110/207 mm, situated intraperitoneally in left iliac fossa, located between ileum and sigmoid colon with intimate contact with them, well defined, with numerous necrosis areas inside. No intra-abdominal adenopathies noted (fig. 4).

In the liver describe the same benign lesions from the ultrasound exam with follow sizes: 17mm, 8mm and 15mm. At the VIII liver segment we detected a 9 mm lesion, between V and VI segments we founded a 29mm lesion and in the VI segment we detected two lesions by 20mm and 23mm suggestive of hepatic metastasis (fig. 5).

Surgery is approached with a median laparotomy. Exploration highlights the origin of the tumor in the sigmoid colon, with invasion to the ileum. The tumor is extremely hemorrhagic at the maneuvering. The tumor was en-bloc resected, with resection of a part of ileum and achievement of an enteroanastomosys and a limited resection of the sigmoid colon because the tumor was started from the serous of the sigmoid colon and also achievement of a coloanastomosys. Surgical recovery was favorable.

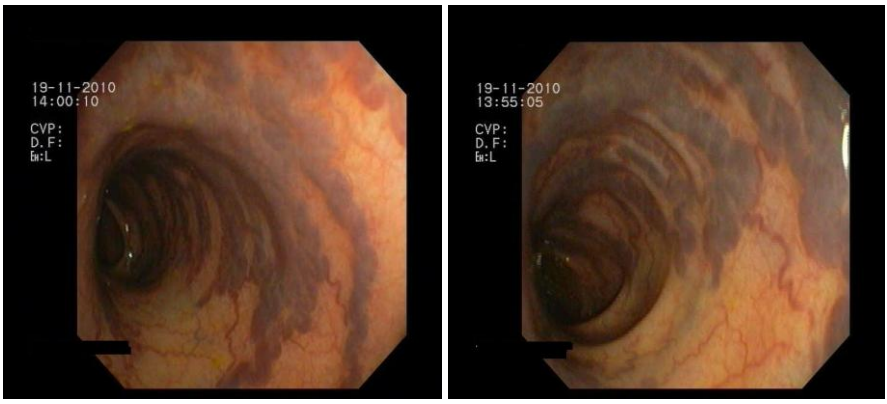

Fig. 3. Colonoscopy exam

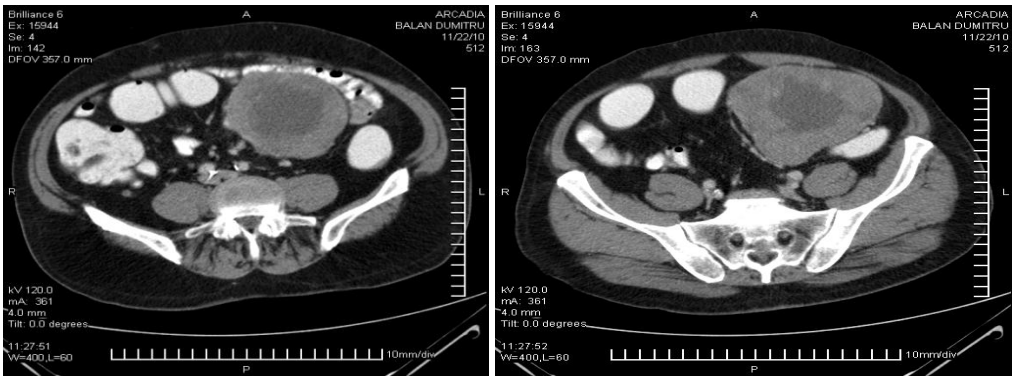

Fig. 4. Computed tomography exam: heterogeneous tumor in left iliac fossa, well defined, with numerous necrosis areas inside

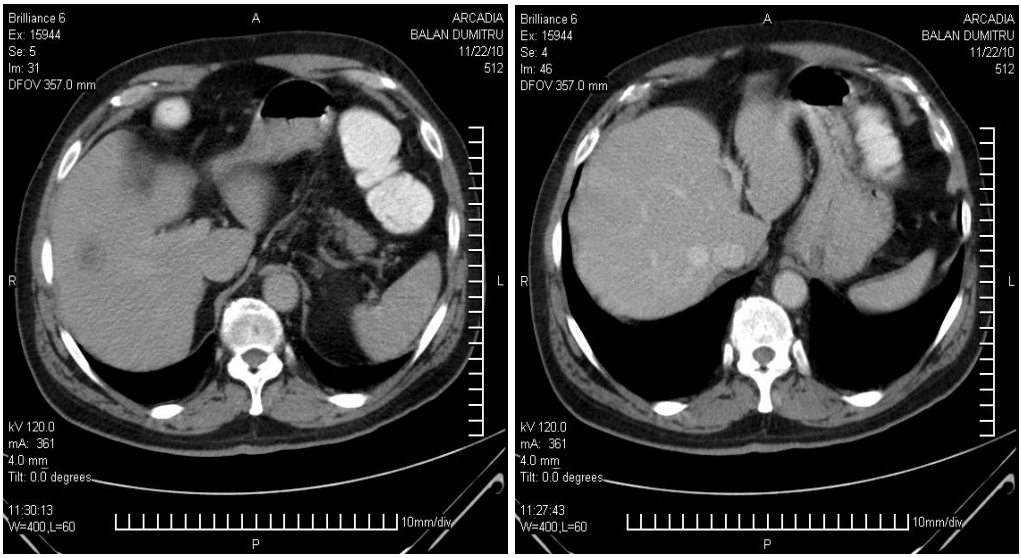

Fig. 5. Computed tomography exam: hemangiomas and liver metastasis

Histopathological appearance of the surgical specimen in HE staining, we used the CD117 antibody (c-kit), as we know that this is a specific marker for GIST (fig. 6).

Another significant marker in the diagnosis of GIST is CD34 antigen. CD34 is a glycoprotein that facilitates the intercellular adhesion or the cellular adhesion to the stroma and it is also positive in the endothelium of blood vessels (fig.7).

For the liver lesions there was no surgical treatment indication and the patient started treatment with Imatinib after 3 weeks from surgical intervention. After one month of treatment liver metastases were transformed into sharply circumscribed, non enhanced homogeneous lesions. After 6 months the aspect of the metastasis was the same.

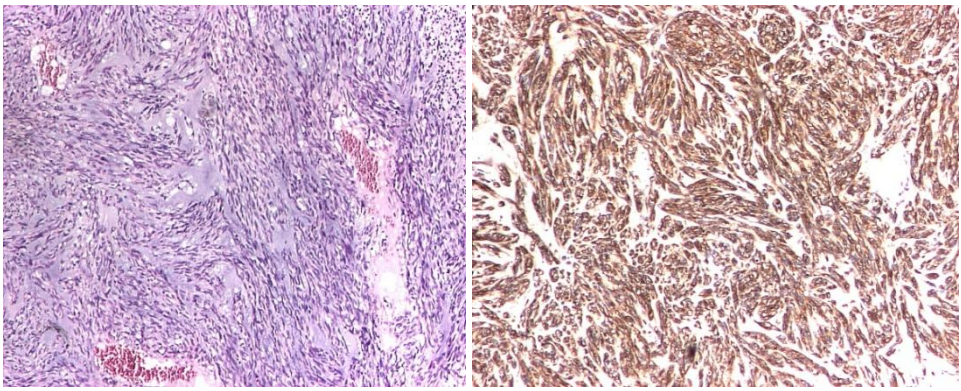

Fig.6. Intense reaction of tumoral cells to this antibody CD117 in colon tissue.

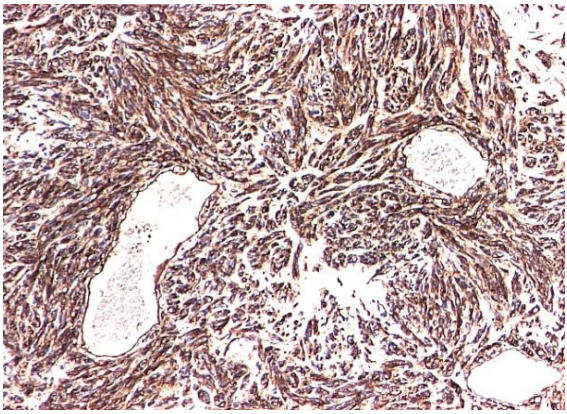

Fig. 7. CD34 positive in the endothelium of blood vessels of colon.

DISCUSSION

Asymptomatic tumors diagnosed at a late stage, which is often the case, can be large on presentation. Prognosis for patients diagnosed with GIST depends on tumor size, mitotic rate, histopathological subtype and tumor location. That is why early diagnosis and R0 resection are the key factors for further treatment and good prognosis (12).

Colonic GIST is even rarer because many of the large bowel GISTs arise in the rectum. Owing to the lack of data on this rare malignancy, the clinical and pathological features of colonic GIST are still unclear (13).

Imatinib mesylate, a tyrosine kinase inhibitor, shows high clinical efficacy in advanced GIST (8, 9) and is now the standard treatment for unresectable and metastatic GISTs (10, 14).

CONCLUSIONS

We reported this case because gastrointestinal stromal tumors (GISTs) developing in the colon are rare. Our patients was symptomatic but mostly nonspecific, most common symptoms were nausea, vomiting, abdominal discomfort, bleeding from the gastrointestinal tract and weight loss and because of that he was diagnosed in the metastatic stage.

LYMPHOMA IN AN HIV-POSITIVE PATIENT (Abstract): HIV/AIDS is considered to be revealing of oncological diseases, of which most frequent are lymphomas. The main causes for this type of disease are non-adherence and non-compliance to antiretroviral therapy (ART). We are hereby presenting a clinical case of lymphoma in an HIV-infected adult, with non-adherence for 30 months. In such a case the interdisciplinary collaboration with the hematologist was essential for the patient's survival. **Keywords**: HIV/AIDS, LYMPHOMA, ANTIRETROVIRAL THERAPY, ADHERENCE.

The HIV pandemic is a reality that is increasingly frequent in Romania. Studies have observed that the median age of HIV-positive patients has slowly shifted from the "pediatric cohort" (born in '87-'89) to adults and even patients over 60 years old (1).

Frequent cases of cancer are observed in patients with severe immunosuppression. Lymphomas are dominant in literature and they require a combined therapy and monitoring by both the infectious diseases doctor and the oncologist (2).

CASE PRESENTATION

We aim to present the case of a patient born in 1979, diagnosed in 2010 (31 years old) with pulmonary tuberculosis. We used two specific tests to screen for HIV: the enzyme-linked immunosorbent assay (ELISA) and antigent-anticorp confirmation test Western Blott. They both were positive. At the very beginning, CD4 cell count was 120/mmc and viral load (VL) 742000 copies/mmc (fig. 1). We applied therapeutic protocol, initiating therapy with tuberculostatics for 10 days. Next we started antiretroviral therapy with zidovudine and lamivudine (AZT+3TC) and efavirenz (EFV). To avoid the immune reconstruction syndrome we administered dexametazone.

Serology for hepatitis B and C were negative, as well as syphilis. Acute phase reactants for citomegalovirus and toxoplasma are were also negative. The resistance report for antiretroviral drugs was negative for all antiretroviral (ART) classes. However, we identified 2 minor mutations: L10V for protease inhibitors and K103R for non-nucleotidic revers-transcriptase inhibitors. We also started prophylaxis for pneumocistosis.

The patient's evolution was favorable. In February 2011 (6 months after diagnosis), CD4 had increased to 414 cells/mmc and the viral load decreased to 160 cop-

ies/mmc.

The patient ended treatment with tuberculostatics after one year, but adherence to ART decreased, up until VL=99900 copies/mmc and CD4=251 cells/mmc in Nov 2012 (fig. 1).

We lost track of the patient for 30 months. In June 2014 the patient presents herself to the Infectious Diseases Hospital with a massive clinical deterioration, with wasting syndrome, loosing over 15 kg in body mass. Also important generalized edema, hypoproteinemia 41.6 g/l, hemoglobin 2.7 g/l, white blood cells 2800/mmc and mononucleosic syndrome present; CD4=58 cells/mmc and VL=54300 copies/mmc (fig. 1). Pulmonary radiological imaging revealed a small amount of pleural liquid, arising the suspicion for pulmonary tuberculosis. This is why our option for antiretroviral therapy consisted of raltegravir (RAL) with abacavir+ lamivudine (KVX) (RAL+KVX), avoiding protease inhibitors. Sputum samples were negative for Koch bacillus (BK) bacterioscopy.

We started support therapy with blood derivates, intravenous aminoacids, albumin, filgastrinum, cotrimoxazol for pneumocystosis prophylaxis and fluconazol for oral candidiasis.

The patient is released from the hospital after 33 days of hospitalization; biological parameters were much emproved – white blood cells 3000/mmc, a normal proteinemia 64.5 g/l, and hemoglobin 9.1 g/l. The patient also gained 4 kg in weight. Renal and hepatic functions were normal.

For the whole duration of the hospital stay, the patient had psychological evaluation and regular counseling sessions. This improved her self-esteem and self-worth, which motivated her to decide for a better adherence to antiretroviral therapy. Through specific techniques (3), the psychologist encouraged the patient to take responsibility for her health-related behavior, thus changing her lifestyle as well.

Two months later, the patient is admitted again with fever and swallowing of latero-cervical lymph nodes. BK cultures were negative, which allowed a switch to last generation antiretroviral molecules – boosted darunavir (DRV/r), etravirine (ETV), abacavir+lamivudine (KVX).

The node biopsy showed mixed cellularity Hodgkins lymphoma; CD4=82 cells/mmc, VL=80 copies/mmc (very close to non-detectable) (fig. 1).

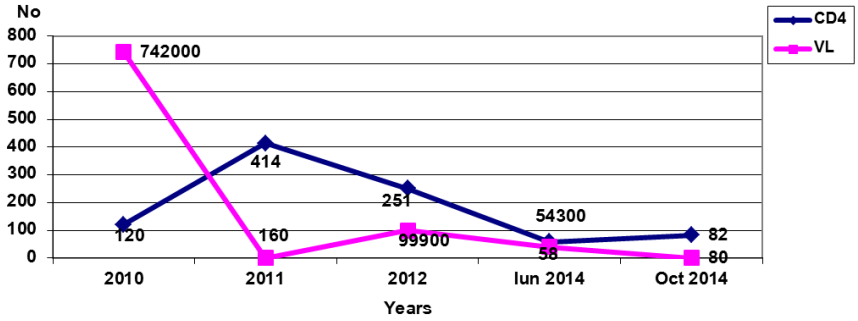

Fig. 1. CD4 cell count and viral load

The clinical and biological aspect of this patient allowed chemotherapy in repeated rounds, but in the presence of substitutive support (blood derivates, filgastrinum, intravenous aminoacids, and albumin).

Latero-cervical lymph nodes decreased

in size. Antiretroviral therapy was continued until present day, keeping this ART scheme for the rest of her life.

DISCUSSION

Immunosuppression with values of CD4<200/mmc is manifested in patients that are non-adherent, non-compliant to ART, in cases of therapeutic fatigue and acquired resistance to highly active antiretroviral therapy (HAART). The Romanian cohort has an extended experience with antiretroviral therapy; patients are multi-experimented and have a history of antiretroviral regimens from the first PIs to last generation molecules (4). The cancer incidence in HIV-positive patients decreased dramatically after 1990, along with the HAART era (5).

From an epidemiological point of view, the risk factors for lymphoma in the United States of America are sex, age and socio-economical status; 80% of people with non-Hodgekin lymphoma are men who have sex with men (MSM) and bisexuals. The high incidence in the East Coast is a reflection of HIV incidence (6).

One of the most significant differences in lymphomas occurring among HIV-infected individuals is a high association with oncogenic herpes viruses. There is a molecular heterogeneity of HIV-related lymphomas. From a pathogenic point of view, this includes mono- or polyclonal subtypes, the presence or absence of the Epstein-Barr virus (EBV) genome and herpes virus 8 genome, which is integrated in the genome of the host cell. The roles of cytokines and tumor suppression genes, as well as the uncontrolled growth of B lymphocytes, are to be further researched. The main hypothesis is that, in the context of HIV immunosuppression, the EBV infection leads to a polyclonal stimulation and the immortalization of B cell clones (7).

Specific antiretroviral therapy is one of the pillars in sustaining the clinical and biological status of the patient, alongside support therapy. A high level of CD4 and a low viral load, as well as balanced biological parameters, assure a better response to specific chemotherapy in lymphomas (8).

CONCLUSIONS

The present case has revealed the importance that adherence to antiretroviral therapy has in the control of the HIV infection. This allowed the possibility to administrate full-dose-intensive chemotherapy regimens with improved patient outcomes.

We found that it is essential that the infectious diseases doctor and the hematologist work together to ensure the best therapeutic solutions to support the HIV patient with lymphoma.

Psychological support and motivational psychotherapy have also been essential in sustaining this patient's desire to go through with therapy. It improved adherence to therapy and generated a change in the patient's lifestyle, as well as a sustained self-esteem and self-worth.

NEWS

A MIXTURE OF CHIA SEED AND POMEGRANATE FRUIT EXTRACTS-SYNERGISTIC EFFECT ON INHIBITION OF MELANIN BIOSYNTHESIS

Fatty acids (especially omega-3 and omega-6) have not only nutritional benefits, but also cosmetic ones. They are involved in many biological functions in the skin (prevention of transepidermal water loss, maintenance of the *stratum corneum* epidermal barrier and disruption of melanogenesis in epidermal melanocytes). *Salvia hispanica* L. (commonly known as chia) seeds are used especially as dietary supplements due to their content in fatty acids and phenolic compounds. The consumption of the seeds decreases the triglyceride and blood glucose levels, thus reducing the risk of heart disease and obesity. *Punica granatum* L. (pomegranate) fruits, rich in polyphenols, have the capacity to reduce melanin content in the skin. Because chia seed oil (rich in α-linolenic and linoleic acids) has high viscosity, low solubility and poor cellular permeability, Diwakar *et al*. have tested a mixture of chia seed and pomegranate extracts (1:1) to reduce melanin content in Melan-a cell culture. The results demonstrated that a mixture containing 25 μL of each extract reduced melanin production by 80% as compared to chia seed extract (10%) and pomegranate fruit extract (40%). The down-regulation of melanogenesis-related genes (Tyr, Tyrp1 and MC1r) could be a mechanism involved in melanin production inhibition, since the mixture did not inhibit tyrosinase activity. The study proved that the mixture of chia seed and pomegranate fruit extracts (1:1) had synergistic effect on melanin inhibition in Melan-a culture cells (Diwakar G, Rana J, Saito L, Vredeveld D *et al*. Inhibitory effect of a novel combination of *Salvia hispanica* (chia) seed and *Punica granatum* (pomegranate) fruit extracts on melanin production. *Fitoterapia* 2014; 97:164-171).

ENDOSCOPIC MANAGEMENT OF CHOLEDOCOLITHIASIS RELATED TO PERIAMPULLARY DUODENAL DIVERTICULA (Abstract): **Aims**: Periampullary duodenal diverticula is a subject still widely debated in the literature. Our study aimed to describe the characteristics and the clinical outcomes of a case series of subjects with periampullary duodenal diverticula and bile duct stones, receiving therapeutic endoscopic retrograde cholangiopancreatography (ERCP), by comparison to patients having only bile duct stones. **Material and methods**: 639 consecutive patients with bile duct stones have been investigated through ERCP during 2011 – 2016 in a single specialized center of gastrointestinal surgery. Periampullary duodenal diverticula (PADD)'s prevalence reached at 16.9% (n=108 cases). The patients with PADD have been compared to those without PADD, by personal characteristics, pathophysiological mechanisms incriminated in producing symptoms and therapeutic outcomes. **Results**: Patients with PADD showed a predominance of males, and a significantly older age. Most frequent abnormality was angulation of the terminal CBD group and jaundice occurred in a significantly higher proportion compared to non PADD group. The percentages of successful selective cannulation and sphincterotomy were significantly lower in the PADD group, even comparable to the literature; meanwhile mechanical lithotripsy was required in a higher proportion of cases. Main cause of failure of cannulation was the changed distal track of the duct. The frequency of postoperative complications was like patients without periampullary duodenal diverticula. **Conclusions**: Therapeutic endoscopic retrograde cholangiopancreatography is obviously a more difficult procedure in the presence of periampullary duodenal diverticula, due to the difficult access to the papilla and the common bile duct, but the success rate remains high even in such cases. **Keywords**: PERIAMPULLARY DUODENAL DIVERTICULA, CHOLEDOCHOLITHIASIS, ENDOSCOPIC RETRO-GRADE CHOLANGIO-PANCREATOGRAPHY (ERCP).

Duodenal diverticula (DD) are known for more than three centuries, the first descriptions belonging to Chomel (1710), Morgagni (1762) and JT Case (1913) (1). Their implications in biliary pathology, especially in syndromes associated with cholestasis (with or without bile duct stones) are known and studied systematically only after introduction into practice of Endoscopic Retrograde Cholangio-Pancreatography (ERCP) in mid-1980. It is also a still widely debated topic in litera-

ture, which is why we present our experience in this regard. Reporting their occurrence depends on the method of diagnosis: 1-6% in patients undergoing a barium transit, 8-12% during an upper gastrointestinal endoscopy, in 15-17% of patients treated by ERCP, about 20-23% after autopsy studies (1).Obviously, the differences between statistics is due to several factors: specific diagnostic accuracy of the method, the type of pathology to which it is addressed, and not least upon the age groups most frequently investigated. Most DD are clinically latent. They rarely produce symptoms, which are usually the consequences of their complications. Of these, the most common are the biliary-pancreatic and more rarely the inflammatory and drilling complications.

Our study aimed to describe the characteristics and the clinical outcomes of a case series of 108 subjects with periampullary DD (PADD) and bile duct stones, receiving therapeutic ERCP in a single specialized center of gastrointestinal surgery, by comparison to patients having only bile duct stones.

MATERIAL AND METHODS

In our clinic, we investigated through ERCP 639 consecutive patients with bile duct stones during 2010 –2015and we found a prevalence of PADD of 16.9% (n=108 cases). We compared the group of patients with PADD to those without PADD, following the personal characteristics (age and gender), the pathophysiological mechanisms incriminated in producing symptoms and the therapeutic outcomes.

As regard the pathophysiological mechanisms, few abnormalities could induce symptoms in DD: 1) angulation of the terminal common bile duct (CBD) with changes in local anatomy and disturbed excretion dynamics of bile and pancreatic juice; 2) compression and stenosis of the terminal portions of the common bile duct and Wirsung duct, with impaired evacuation and dilated CBD; 3) impaired duodenal peristalsis and 4) incomplete evacuation of the diverticular bag, exacerbating the local microbial flora (2). These abnormalities usually induce biliary-pancreatic symptoms like: jaundice, cholangitis, recurrent acute pancreatitis or diverticulitis and perforation. We considered the presence of all these symptoms in the study, as binary variables.

The therapeutic outcomes included the ERCP performance (with focus on the technical and tactical problems found during sphincterotomy), the occurrence of complications and the length of hospitalization. For measuring the ERCP performance we followed the proportion of patient receiving selective cannulation and sphincterotomy in each group and the proportion of cases which required mechanical lithotripsy. As complications, we followed the acute pancreatitis (classified as mild, medium and severe) and post ERCP hemorrhage.

At admission, all patients were investigated following a protocol that included clinical exam, biochemical tests (blood counts, liver and pancreatic tests, coagulation and renal function), electrocardiogram and thoracic-pulmonary radiography. After ERCP, at 24-48 hours, blood count and serum biochemistry tests were repeated to identify possible post-procedural complications. Antibiotic therapy was indicated in patients with vascular prostheses, heart valves or immunosuppressed status. Piperacillin-tazobactam was administered 12 hours before and 24 hours after ERCP. The endoscopic procedure was performed under sedation with propofol and midazolam (3).

If during the same session laparoscopic cholecystectomy for gallstones was performed, the patients received anesthesia with endotracheal intubation.

The data were analyzed using descriptive statistic techniques. The continuous variables were assessed for normality using the Kolmogorov-Smirnov test. The scale variables were discussed as mean ± standard deviation (SD) and as medians (25th, 75th percentile). T Student-test was used for comparison. A p-value <0.05 was considered for statistical significance (two tailed test). Categorical data were presented as proportions with one decimal. Proportions were compared by using Chi square or Fisher exact tests. Statistical analysis was performed with the SPSS 23.0 and Open Epi.

RESULTS

The personal characteristics: The subjects with PADD tended to have a predominance of males and to be significantly older compared to the subjects without PADD (males 65% in PADD group *vs.* 35% in non PADD group, p<0.001).In the PADD group, females tended to be significantly younger compared to males (females median age 54 vs. males median age 64, p<0.001). Generally, it is considered that the clinical manifestations of the presence of DD occur after the age of 60, being correlated with the duration of the biliary disease and the PADD diameter. In our PADD group, only 52.8% of the subjects were older than 60 years, with a clear predominance of the females in younger ages (ratio males/females 0.5-1.9).

PADD had been diagnosed before the endoscopic procedure in only 50 patients, among which 23, 17, 5 after axial upper gastrointestinal endoscopy, computed tomography, barium transit and MRI cholangiography respectively. Of these, five were less than 40 years old. Colonoscopy has been performed in 21 of the subjects due to some digestive symptoms and colon diverticulosis has been identified 17 patients (among which 14 older than 60 years).

The pathophysiological mechanisms incriminated in producing symptoms: We found in our study significantly higher frequency of abnormalities in the PADD group compared to non-PADD subjects (4). Most frequent abnormality in the PADD group was angulation of the terminal common bile duct (CBD), followed by compression and stenosis of the CBD and Wirsung duct, impaired duodenal peristalsis and incomplete evaluation of the diverticular bag.

In the non-PADD group, most common was compression, followed by angulation and impaired peristalsis, but, as mentioned, all abnormalities occurred in a significantly lower proportion (5). Among the symptoms induced by the pathophysiological mechanisms (jaundice, cholangitis and recurrent acute pancreatitis), only jaundice occurred in significantly higher proportion in the PADD group. According to the literature, jaundice is usually moderate (with a bilirubinemia of 4-8 mg/dl), but it can be persistent or wavy, being produced by disturbed bile elimination, compression of CBD, ampulla dysfunction, concomitant bile stones and cholangitis (6). In our study, 77.8% of the PADD subjects had jaundice (moderate in most cases), compared to 42% of patients without PADD. Cholangitis was diagnosed based on clinical symptoms (Charcot-triad: pain, fever, jaundice), clinical investigations and laboratory examinations. It occurred in similar frequency in both groups. Most of the cases with cholangitis had prolonged episodes of low grade fever, occasional vesperal chills – all of them signs of torpid, subacute, slow-

evolving cholangitis. Also, similar frequency was found for recurrent acute pancreatitis. Diverticulitis and perforation - in general, inflammation, ulceration and even perforation of the diverticular wall can occur (commonly retroperitoneal, less intraperitoneal), due to food stasis. We recorded 7 cases of diverticula with intense mucosal congestion, crumbly and easy bleeding. At those specific maneuvers of ERCP these cases had a high risk of bleeding and perforation (7).

TABLE I.
Pathophysiological mechanisms and complication involved in PADD and non-PADD groups

	PADD Group		Non-PADD Group		p-value*
	No	%	No	%	
Pathophysiological mechanisms					
Angulation of the terminal common bile duct	84	77.8%	90	16.9%	<0.001
Compression and stenosis of the terminal portions of the common bile duct and Wirsung duct	62	57.4%	128	24.1%	<0.001
Impaired duodenal peristalsis	42	38.9%	54	10.2%	<0.001

Cholangitis	37	34.3%	181	34.1%	0.972
Recurrent acute pancreatitis	9	8.3%	57	10.7%	0.455
Diverticulitis	7	6.5%	NA	NA	NA

*Chi^2 test

***Acute biliary symptoms in pregnant women*:** Beside the above-discussed symptoms, we noticed that five patients who required ERCP for biliary pain induced by PADD were women aged between 30 and 43 years. Three of these women were pregnant - one in the first and the other two in the second trimester of pregnancy. For these patients, emergency ERCP was motivated by the presence of CBD stones complicated by repeated episodes of acute cholangitis (two cases) or acute biliary pancreatitis due to intrapapillar impacted stone (one case). Sphincterotomy, clearance of CBD and prosthesis were made without fluoroscopic control. In all three cases, the pregnancy was carried to term without obstetric complications. After birth, the patients were again investigated (biochemical and imaging) and no residual CBD lithiasis was found. Laparoscopic cholecystectomy was performed in the same operating time.

***ERCP performance*:** Usually, the first step of ERCP is CBP selective cannulation associated or not with "pre-cut" papillotomy (8, 9). In our study, this step was conducted with a standard pull-type sphincterotomy, which was later replaced by a guide wire. We succeeded to perform selective cannulation in 94.4% and 98.9% of PADD and non-PADD patients respectively. No pancreatic sphincterotomy was been done. After performing the cholangiography, most patients require papilo-sphincterotomy for the extraction of stone, especially in patients with

PADD inducing biliopancreatic suffering (10). In our study, papilo-sphincterotomy has been performed in 88.9% and 97% of PADD and non-PADD patients. Normally, this should be followed by appropriate extraction of stones, papilla and terminal CBD prosthesis. Mechanical lithotripsy could be required. As seen in table II, both selective cannulation and papilo-sphincterotomy were performed in slightly lower proportion in the PADD group, meanwhile mechanical lithotripsy was required in a higher proportion of cases.

In four cases from the PADD group we were not able to perform sphincterotomy due to abnormalities in the profound position of the papilla (11). In other two patients, we performed only autostatic balloon dilatation (younger patients, less dilated common bile duct, reduced diameter calculi). Extraction of stones was performed using probes with basket-type slumber. Mechanical lithotripsy was required for calculi over 12 to 15 mm diameter or even less if sphincterotomy was limited by local anatomical changes (12, 13).

TABLE II.
ERCP performance in PADD and non-PADD groups

	PADD Group (N=108)		Non-PADD Group (N=531)		p-value
	No	%	No	%	
Selective cannulation	102	94.4%	525	98.9%	0.016*
Papilo-sphincterotomy	96	88.9%	515	97.0%	0.001*
Mechanical lithotripsy	17	15.7%	42	7.8%	0.010**

* Fisher exact test; ** Chi^2 test

Complications. The frequency of acute pancreatitis was slightly higher in PADD group, but without statistical significance: 24 (22.2%) and 97 (18.3%) cases in PADD and non-PADD groups respectively, p=0.339, Chi^2 test. They appeared to be attributable to accidental clouding of the Wirsung (12 patients) and to sphincterotomy (12 cases). In both groups (PADD and non-PADD) most cases of acute pancreatitis were mild, limited to biochemical expression and with quick resolution in 24-48 hours (19 and 74 in PADD and non-PADD groups respectively). All patients received indomethacin postoperatively. The medium or severe forms, requiring specific treatment, occurred in similar proportion in both groups (p=0.99, Fisher exact test). Post ERCP hemorrhage occurred in 4 and 13 cases respectively in PADD and non-PADD group (p=0.64, Fisher exact test). Neither other complications specific to ERCP, nor deaths related to ERCP procedure were registered in our study. Length of hospitalization was also similar between groups with a median of 3 days (min 1, max 14 days, p=0.34, Mann Whitney U test).

DISCUSSION

In our study, the patients with PADD were cured using ERCP in slightly lower proportion compared to those without PADD, the results being still comparable to the literature. Few factors could contribute to this lower performance of ERCP.

Firstly, we should consider the position of the diverticula. In terms of relations with the papilla of Vater the diverticula may be juxta-ampullary - when the papilla is adjacent 1 to 2 cm to the diverticulum, or peri-

ampullary - containing both the papilla and bile duct intramural. The chance of generating biliary diseases is more reduced in juxta-ampullary diverticulum, but the periampullary one is most common variety and correlated directly with extrahepatic biliary pathology. Papilla can be located anywhere in the diverticulum, but most commonly it is on the floor. More rarely, we can find one of the side walls of DD. In our case series, all DD were located periampullary (14).

The first step of ERCP, the selective cannulation of CBD, is potentially more difficult in patients with PADD (15). In our study, CBD catheterization average time was 6.6±3.14 minutes compared to only 4.0±2.12 minutes in patients without PADD. Sometimes the papilla of Vater is "pulled" into the DD, its pore is often hidden, diverted down or sideways. The direction of the sphincterotomy is essential to be properly judged in relation to the common bile duct intramural axis, and its length to be correlated with the projection of the papilla. The terminal juxta-ampullar CBD is often strongly angled, making selective cannulation difficult. In our study, this was observed in 48 patients diagnosed with PADD (44%), compared to only 14% in the overall group of non-PADD patients. The changed path of the distal CBD represented the main cause of cannulation failure (16).

We faced technical and tactical problems during sphincterotomy: The correct orientation of sphincterotomy in a distorted papilla, with deeply modified anatomical ratios – 81 (75.0%) versus 59 (11.1%) PADD and non-PADD groups respectively ($p<0.001$, Chi^2 test). The hardest part was the approach of a deeply located papilla (in the cavity of a DD) - 39 patients, (36.1%). The room for maneuver in this case is very narrow. The second difficult selective catheterization was when the papilla was located on one of the side walls of the PADD - 42 patients, (38.9%). The depth of the sphincterotomy was difficult to assess, due to the thin DD wall. The landmarks are the ridge of the actual papilla and the cholangiographic appearance of the juxta-ampullary region. The classical landmark for the limit of incision is the mucosal suprapapillary. The depth of sphincterotomy is generally limited, which explains the lower rates of stones extraction. The average time for sphincterotomy was 4.9±2.17 minutes in the PADD group versus 3.2±1.56 minutes in non-PADD group.

CONCLUSIONS

In our study PADD were associated with an obvious predominance in males but seemed also to become symptomatic in younger age for females.

The mechanisms implied most frequently in the biliary-pancreatic pathology were angulation, compression and stenosis of the terminal portions of the common bile duct and Wirsung duct, with impairment of bile drainage and pancreatic secretion. By this, favorable conditions for lithogenesis, cholangitis, jaundice and chronic pancreatitis are created. Incomplete evacuation of the diverticular bag exacerbates local microbial flora, becoming a possible source of colonization upward the CBD.

Performing ERCP was obviously more difficult in the presence of PADD. The percentages of successful selective cannulation and sphincterotomy were slightly lower in the PADD group compared to patients having only CBD stones, even comparable to the literature. Proportion of post ERCP complications was similar in both groups. These results can be reached only by accuracy, experience and meticulous execution of maneuvers. Our experience with the pregnant women showed that,

when necessary, ERCP can be performed safely during pregnancy and without important risk for mother or child.

Our experience proved that therapeutic endoscopic retrograde cholangio-pancreatography obviously a more difficult procedure in the presence of periampullary duodenal diverticula, due to the difficult access to the papilla and the common bile duct, but the success rate remains high even in such cases.

FIBROSIS ASSESSMENT IN CHRONIC HEPATITIS C – IS THE LIVER BIOPSY STILL NECESSARY? THE PATHOLOGIST POINT OF VIEW (Abstract): **Aim**. The aim of this study was to compare the histological stage of fibrosis determined by liver biopsy with the stage of fibrosis assessed by *Fibroscan*, to analyze the correspondences and inconsistencies between obtained values and to discuss the role of the microscopic exam, from the pathologist point of view. **Material and methods.** The study group consisted of 185 patients diagnosed with chronic hepatitis. Serological tests diagnosed chronic hepatitis C in 183 patients, and chronic hepatitis B and C for 2 patients. The patients were evaluated to determine the stage of fibrosis using two methods: liver biopsy and elastography (*Fibroscan*). **Results.** Based on the pathologic evaluation, 124 cases were diagnosed as moderate chronic hepatitis (score 6 – 8), and the remaining 60 cases as severe hepatitis (score 9 – 12). Comparison of data from examination of liver biopsy with that obtained by *Fibroscan* examination revealed overlapping and divergent aspects. The fibrosis stage established through liver biopsy did not always coincide with the one assigned by liver stiffness measurement, particularly for intermediate stages F2 and F3. The best overlap was noted for F0–F1 and F4 stages, which indicates the evident ability of transient elastography to separate patients with minimal or no fibrosis from patients with extensive fibrosis. **Conclusions**. Our data concurs with the literature, which confirms presence of differences between *Fibroscan* and biopsy. From the point of view of the pathologist, liver biopsy still remains a valuable instrument, offering a relevant image of liver changes – as it is regarded more rather a selective than routine technique.
Keywords: LIVER BIOPSY, CHRONIC HEPATITIS, FIBROSIS

A common feature of all chronic viral hepatitides caused by hepatotropic viruses is formation of a glycoprotein network instead of normal glycolipoprotein one (1). As liver function is impaired, the assessment of fibrosis is essential in the decisions taken for the initiation of treatment, in the appraisal of treatment response and screening for liver cancer (2-7).

Liver biopsy classically represents the gold standard in the evaluation of the pathological lesions specific for chronic hepatitis – including the staging of fibrosis by the application of various existing scoring systems (8-13). However, the procedure has a series of disadvantages: it is invasive, expensive and the results may be influenced by sampling errors and intra– and interobserver variability (14).

Therefore, through concerted concerns of hepatologists, non–invasive methods based on physical approach have been de-

veloped in the past 15 years, in order to provide similar assessment of the lesions. These methods measure liver stiffness by ultrasound or magnetic resonance elastography and they were immediately implemented in diagnosis practice due to their non–invasiveness (14, 15). Consequently, several research reports have examined in correlation the advantages and limitations of the pathological and elastographic evaluation. Although many papers show positive correlation between the liver stiffness established by transient elastography and fibrosis stage determined by biopsy (16-19), the correspondence of results is not absolute. Consequently, it cannot be firmly stated that elastography could represent a surrogate for biopsy (20-23). Most experts believe that non–invasive techniques may not replace completely liver biopsy, but they may contribute to the decrease of the number of required biopsies (24, 25, 26).

The aim of this study was to compare the histological stage of fibrosis determined by liver biopsy with the stage of fibrosis assessed by *Fibroscan*, to analyze the correspondences and inconsistencies between obtained values and to discuss the role of the microscopic exam, from the pathologist point of view.

MATERIAL AND METHODS

The study group consisted of 185 patients diagnosed with chronic hepatitis at The Institute of Gastroenterology and Hepatology Iaşi, between 2007 and 2010. Serological tests diagnosed chronic hepatitis C in 183 patients, and chronic hepatitis B and C for 2 patients.

The patients were evaluated to determine the stage of fibrosis using two methods: liver biopsy and elastography (*Fibroscan*). Liver biopsies were processed in Pathology Department, University of Medicine and Pharmacy "GrigoreT.Popa" Iaşi. Histological sections were stained with Haematoxylin–Eosin and Van Gieson colorations in order to reveal and stage fibrosis according to METAVIR score.

The elastography with *Fibroscan* was performed at the Institute of Gastroenterology and Hepatology, Iaşi. In the determination of tissue elasticity, threshold valuesare 7.1 kPa for F≥2, 9.5 kPa for F≥3 and 13 kPa for F = 4 (fibrosis stage determined according to METAVIR score) (13, 22, 27).

RESULTS

Based on the pathologic evaluation, 124 cases were diagnosed as moderate chronic hepatitis (score 6–8), and the remaining 60 cases as severe hepatitis (score 9–12).

Comparison of data from examination of liver biopsy with that obtained by *Fibroscan* examination revealed overlapping and divergent aspects.

In the 3 cases with chronic moderate hepatitis with necro-inflammatory activity score 6, the diagnosis of fibrosis stage coincided between pathological and *Fibroscan* exam.

In the 28 cases with chronic moderate hepatitis, necro-inflammatory activity score 7, the fibrosis stage was consistent only in 4 of the 15 cases assigned F0 – F1, the other 11 cases being evaluated by *Fibroscan* with more severe fibrosis stages (F2, F3, F4); none of the 11 cases assessed as F2 and the 2 cases evaluated as F3 by the pathological investigation received a similar fibrosis stage by *Fibroscan* exam, which was less or higher.

In the 94 cases with chronic moderate hepatitis, necro-inflammatory activity score 8, fibrosis stage was consistent in only 27 of the 51 cases assessed as F0 – F1, the other 24 cases evaluated by *Fibroscan*

receiving more severe fibrosis stages (F2 – 13 cases, F3 – 7 cases, F4 – 4 cases). Diagnosis overlapping was recorded in 8 of the 35 cases classified as F2, the other 27 presenting after evaluation by *Fibroscan* fibrosis stage F0 – F1 – 9cases, F3 – 6 cases and F4 – 9 cases; for 3 cases, the comparative evaluation was not possible. Also, fibrosis stage F3 was consistent in 2 of 8 cases, the other 6 presenting after the evaluation by *Fibroscan* fibrosis stage F0 – F1 – 3 cases, F2 – 1 case and F4 – 2 cases.

TABLE I

Parallel assessment of the stage of fibrosis by liver biopsy and elastography

				F4	2

In the 32 cases with chronic severe hepatitis, necro-inflammatory activity score 9, fibrosis stage diagnosis was consistent only in 2 of the 4 cases assessed as F0–F1, the other 2 cases being evaluated by *Fibroscan* with more severe fibrosis stages (F2 – 1 case, F4 – 1 case); also, it was consistent in 5 of the 13 cases classified as F2, the other 8 being assessed by *Fibroscan* as fibrosis stage F0 – F1 – 4 cases, F3 – 2 cases, and F4 – 2 cases; finally,diagnosis was consistent for 3 of the 15 cases assigned as F3, the other 12 cases presenting according to assessment by *Fibroscan*, fibrosis stage F0–F1 – 2 cases, F2 – 2 cases and F4 – 7 cases; in 1 case, the comparative evaluation was not possible.

In the 16 cases with chronic severe hepatitis, necro-inflammatory activity score 10, there was no concurrence for stage F0 –

F1. The fibrosis stage was consistent only in 1 case of the 5 cases assessed as F2, the other 4 cases presenting fibrosis stage F3 – 2 cases and F4 – 2 cases when assessed by *Fibroscan*. Fibrosis stage diagnosis was consistent only in 2 of the 9 cases classified as F3, the other 7 presenting fibrosis stage F0 – F1 – 2 cases and F4 – 5 cases in the evaluation by *Fibroscan*.

In the 9 cases with chronic severe hepatitis, necro-inflammatory activity score 11, there was no overlap for F0, F1 and F2 stage. Fibrosis stage diagnosis was consistent only in 2 cases of the 5 cases assessed as F3, 2 cases presenting after *Fibroscan* evaluation fibrosis stage F4 – 2 cases, while for 1 case the evaluation was impossible. Fibrosis stage diagnosis was consistent only in 1 case of the 2 assigned as F4, the other case being evaluated by *Fibroscan* as F3.

In the 3 cases with chronic severe hepatitis, necro-inflammatory activity score 12, there was no overlap between histological stage F3 and the stages assesed by *Fibroscan* (F0 – F1 – 1 case, F4 – 2 cases) (tab. I).

DISCUSSION

The Pathology Department of University of Medicine and Pharmacy „Grigore T. Popa" Iaşi has an old tradition in the field of liver biopsy diagnosis, as a result of the close relationship with the Institute of Gastroenterology and Hepatology Iaşi. Pathologic evaluation was joined, after the year 2000 by the investigation through specific imagistic methods (transient elastography) performed by the gastroenterologists in the Institute (28-31).

By the assessment of the stiffness in liver tissue the imagistic noninvasive methods allow for the identification and quantification of fibrosis degree in hepatitis and cirrhosis (14,15,29-31). As they are non–invasive, easily accepted by patients, quick and reproducible, non–invasive methods replaced gradually liver biopsy – because they are regarded as alternatives for diagnosis, on the basis of their relatively similar efficiency (14,29,30).

The implementation of these methods in current diagnosis practice is based on reliable evidence which certify the presence of a close correlation between elasticity of liver parenchyma and stage of fibrosis. This evidence represents the result of wide studies that compared the fibrosis stage provided by non–invasive imagistic methods with the stage determined by pathology (16-19, 33, 34). Moreover, there are other clinical data that challenge the necessity of liver biopsy for staging fibrosis prior to antiviral therapy in chronic hepatitis B (31, 32).

Hence, liver biopsy lost its traditional status as gold standard.

The question to be asked is whether it can be completely replaced by the new technologies. The answer is negative.

The analysis of our results reveals that the fibrosis stage established through liver biopsy does not always coincide with the one assigned by liver stiffness measurement (*Fibroscan*), particularly for intermediate stages F2 and F3. The best overlap was noted for F0–F1 and F4 stages, which indicates the evident ability of transient elastography to separate patients with minimal or no fibrosis from patients with extensive fibrosis. Our data concurs with the literature, which confirms the presence of differences between *Fibroscan* and biopsy (19). Although numerous studies focused on the efficiency of non–invasive tests (sensitivity, specificity, accuracy and prediction) (17-19, 33-35) support their diag-

nostic value, liver biopsy remains a reliable method (36).

Even if the role of liver biopsy as a diagnostic test is fading, the role in establishing prognosis is unquestionable (37). Microscopic aspects supply a relevant image for the general characterization of liver changes. The context of liver damage is interpreted through the correlation with the necro–inflammatoy activity that leads to fibrosis and by association with alterations in hepatocytes, other cell population or biliary canalicules (38). From the point of view of the pathologist, liver biopsy represents a valuable instrument (36), as it is regarded as rather a selective than routine technique (39).

CONCLUSIONS

Liver biopsy is no longer considered the gold standard in the assessment of fibrosis from the hepatitis context, but the morphologic information which reveals the underlying background of lesions associated with chronic hepatitis cannot be ignored. The development of new technologies reflects directly in the selectivity of recommendations for liver biopsy.

NEWS

THE UTILITY OF LIPOPOLYSACCHARIDE-BINDING PROTEIN IN THE DIFFERENTIATION BETWEEN PERIPROSTHETIC JOINT INFECTION AND ASEPTIC LOOSENING?

The pre-operative differentiation between periprosthetic joint infection (PJI) and aseptic loosening after total hip (THA) or knee (TKA) arthroplasty is essential for successful therapy and relies in part on the use of molecular markers. A recent prospective, controlled, clinical trial study conducted by Friedrich MJ and collaborators assessed serum levels of lipopolysaccharide-binding protein (LBP) from one hundred and twenty patients presenting with a painful TKA or TKA with indication for surgical revision. Pre-operative blood and serum samples were collected and analysed also for white blood cell (WBC) count and C-reactive protein (CRP). The definite diagnosis of periprosthetic joint infection was determined on the basis of clinical, microbiological and histopathological examination. LBP showed significantly higher values in PJI compared with aseptic loosening ($p < 0.001$) and control ($p < 0.001$), with a specificity of 66 % and a sensitivity of 71 % at a cutoff value of >7 ng/ml. In combination with CRP, the positive predictive value for PJI was at 0.67; nega-tive predictive value with both negative was at 0.77. the authors concluded that the use of LBP in serum appears not to be a more accurate marker than CRP level in serum for detect-ing PJ, and on the basis of these results, they cannot recommend the sole use of LBP for dif-ferentiating PJI and aseptic loosening following THA and TKA. (Friedrich MJ, Randau TM, Wimmer MD et al. Lipopolysaccharide-binding protein: A valuable biomarker in the differ-entiation between periprosthetic joint infection and aseptic loosening? *Int Orthop*. 2014 May 15. [Epub ahead of print]. PMID:24827968).

MANAGEMENT DILEMMAS OF RETROPERITONEAL PARAGANGLIOMA: REPORT OF A CASE (Abstract): A 17-year-old boy presented to emergency department with abdominal pain in the left upper quadrant along with a palpable mass. A CT scan revealed a 10 x 8.5 cm mass in the retroperitoneal area, suggestive of a sarcoma. The patient underwent surgical resection of the lesion, the histological examination of which confirmed a paraganglioma. An ^{131}I-Metaiodobenzylguanidine (MIBG) scan excluded distant metastasis. Paragangliomas are rare tumours of the neuroendocrine system and certain considerations are pivotal in the management of these tumours. Urinary and plasma catecholamines measurement along with CT, MRI, and MIBG scanning facilitate diagnosis, localisation and characterisation of these tumours. Surgical excision is the treatment of choice for both primary and recurrent tumours. Unfortunately, histological characterisation for malignancy is limited and these tumours are considered malignant upon development of metastasis or local recurrence. Inexistence of histological criteria for malignancy means a long-term surveillance is the norm in these patients. **Keywords:** ADOLESCENT, PARAGANGLIOMA, RETROPERITONEAL

Paragangliomas are the rare tumours arising from the extra-adrenal neuroendocrine cells (1). Most paragangliomas occur in head and neck region and occurrence at other sites including the retroperitoneal area is relatively uncommon (1,2). Although a familial predisposition has been described, these tumours are seldom considered in healthy teenagers (3). We report a case of an adolescent boy who presented with severe abdominal pain and a palpable mass. The diagnosis was established on histological examination of the tumour. This report is aimed at discussing certain diagnostic and management challenges, and providing the clinicians with a concise account of how to address those.

CASE REPORT

A previously healthy 17-year-old boy attended the emergency department with severe abdominal pain of a day's duration. A physical examination revealed a palpable mass in the left upper quadrant of the abdomen. The patient was apyrexial and full blood count, urea and electrolytes

were unremarkable. On a CT scan, the mass appeared to be a heterogeneous tumour in the retroperitoneal area in close proximity to pancreatic tail and descending colon, measuring 10 x 8.5 cm. The tumour appeared to be a retroperitoneal sarcoma containing areas of calcification and with internal haemorrhage. Angiographic embolisation of the rich vascular arcade derived from the inferior mesenteric, subcostal, and lumbar arteries was achieved preoperatively to minimise the blood loss. At operation, the mass was found to be an encapsulated, highly vascular tumour occupying the left half of retroperitoneal area and adherent to the upper descending colon (fig. 1). Complete removal of the tumour was performed along with segmental resection of the involved descending colon. The histological examination of the tumour showed the features consistent with a paraganglioma.

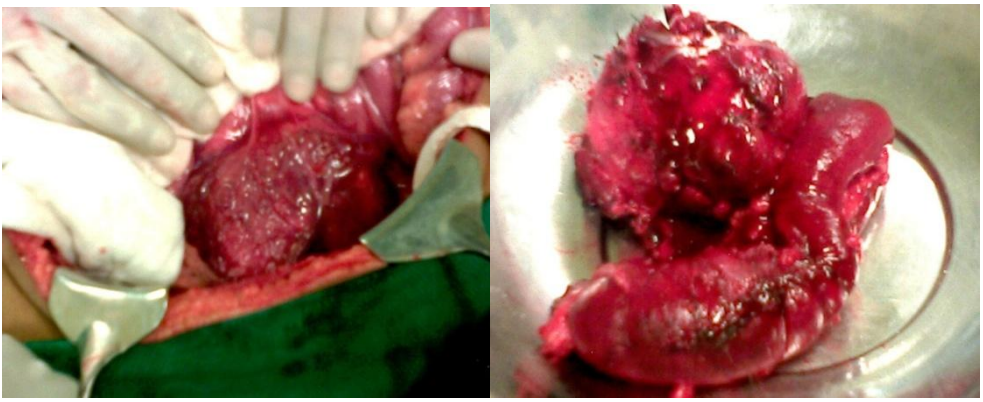

Fig. 1. Retroperitoneal extra-adrenal paraganglioma.
Left: In-situ tumour appears adherent to descending colon. **Right:** The resected specimen consisting of the involved segment of descending colon along with paraganglioma

The patient made an un-eventful recovery in the postoperative period and was discharged home on the 5th day after operation. A subsequent ^{131}I- Metaiodobenzylguanidine (MIBG) scan in the early postoperative period excluded distant metastasis. Clinically, the tumour was considered benign in view of the non-metastatic disease, as discussed below. Nevertheless, the patient will require a long clinical follow-up due to inexistence of definable histological criteria for malignancy in paragangliomas.

DISCUSSION

The paragangliomas arise from the neural crest cells lying outside adrenal medulla. These tumours originate both in the hereditary as well as the sporadic form and are most commonly diagnosed in the fourth or fifth decade of life (3, 4). Anatomically, these tumours occur anywhere from upper neck to pelvic floor, however, head and neck remain the commonest regions affected (4, 5). Retroperitoneal paragangliomas usually develop in sympathetic paraganglia and at least half of these secrete catecholamines. Such tumours are called functional paragangliomas. It has been reported that up to half of the abdominal paragangliomas are malignant (5). The common presenting features include abdominal mass, pain, palpitations, headache, sweating, hyperten-

sion, and genitourinary symptoms (2, 5, 6).

The diagnosis is established by measurement of the urinary and plasma catecholamines, radiological findings of tumour on CT or MRI scan, and ^{123}I- or ^{131}I-MIBG scanning for functional paragangliomas (5, 7). Tumour localisation has improved remarkably owing to the use of different imaging modalities. Unfortunately, the histological examination is limited by its inability to distinguish between benign and malignant tumours, and tumour recurrence or metastasis are generally accepted as features of the malignant paragnagliomas (8, 9). Therefore, these patients usually require a long clinical follow-up. Annual biochemical testing, CT or MRI scan, and MIBG scintigraphy are essential in the follow-up process to diagnose recurrence, delayed appearance of multiple tumours, or metastasis (4, 7, 8).

Surgical excision remains the mainstay of treatment for both primary and recurrent tumours (1, 4, 5, 7). Feasibility of the laparoscopic approach has been reported albeit open resection remains the commonest operative strategy (4, 10). The functional tumours require reversal of circulating catecholamines prior to the operation. Both alpha and beta antagonistic drugs are used preoperatively to control blood pressure and to prevent intraoperative hypertensive crisis (4, 7). Radiotherapy or chemotherapy may be used for preoperative debulking of tumour. Ablation of the tumour with high dose I-131 MIBG has shown promising results and more evidence is awaited (5, 11).

The abdominal paraganglioma is an uncommon condition in adolescents (6, 12). Therefore, it remains a rare clinical consideration in previously healthy teenagers presenting with abdominal pain. In managing such cases, a degree of suspicion should be maintained for uncommon pathologies like neuroendocrine tumours. A careful clinical assessment cannot be overemphasized which would help detect an associated mass. Absence of acute inflammatory markers should trigger instigation of further investigations, the most appropriate being a CT or an MRI scan. It is vital that such cases are assessed and managed on an individual basis given the implications of misdiagnosis.

CONCLUSIONS

Extra-adrenal retroperitoneal paraganglioma presents diagnostic and management challenges and, once suspected, certain management considerations are pivotal. A careful clinical assessment differentiates it from common causes of pain in this age group. The urinary and plasma catecholamines measurements along with CT, MRI, and MIBG scanning should be employed to diagnose, localise and characterise these tumours. Surgical excision is the treatment of choice for both the primary and the recurrent tumours. Inexistence of histological criteria for malignancy means a lifelong surveillance is the norm in these patients.

NEWS

NEW APPROACH IN TREATMENT OF MULTIDRUG-RESISTANT TUBERCULOSIS

Multidrug-resistant tuberculosis (MDR-TB) is a major problem health concern. According World Health Organization (WHO), in 2012, MDR-TB accounted for 3.6% of new cases and 20% of previously treated cases of TB (1). Therapy for MDR-TB is long, hard and expensive with antiquated drugs. After 40 years, a new antituberculosis drug – bedaquiline - has become available for use. Bedaquiline is an inhibitor of mycobacterial ATP synthase with bactericidal activity. A recent clinical trial, which included 160 new cases of MDR-TB treated with bedaquiline in combination with background treatment, showed that the patients who received bedaquiline have had a median time to sputum-culture conversion by 83 days, with 42 days shorter than placebo group. Also, bedaquiline used in therapeutic regimen for MDR-TB determined an increase of rate of culture conversion at 24 weeks (79%) and at 120 weeks (62%) compared with placebo (58% respectively 44%). The same study showed that the risk of acquiring new resistance to anti-TB drugs was lower in patients treated with bedaquiline (2). These findings support the use of bedaquiline in MDR-TB treatment (World Health Organization. Global tuberculosis report 2013. www.who.int/tb/publications/global_report/en/; Diacon AH, Pym A, Grobusch MP et al. Multidrug-resistant tuberculosis and culture conversion with bedaquiline. *N Engl J Med*. 2014;371:689-691, 723-732).*Cătălina Luncă*

THE IMPORTANCE OF RENAL BIOPSY IN THE MANAGEMENT OF RENAL TRANSPLANTATION

G. Veisa[1], C. Adelina-Iuliana Bîrlescu[2], D. Siriopol[1]

University of Medicine and Pharmacy "Grigore T. Popa"- Iaş i

2. Clinic of Nephrology

THE IMPORTANCE OF RENAL BIOPSY IN THE MANAGEMENT OF RENAL TRANSPLANTATION (Abstract): Renal biopsy remains the"gold standard'' for the diagnosis of renal allograft dysfunction. The aim of our study was to highlight the importance of renal biopsy in the management of allograft dysfunction (early diagnosis and therapeutic approach). Our study included 23 renal allograft biopsies from 20 patients. This retrospective study analyzed the demographic and clinical data, histological results and the evolution of renal function under the immunosuppressive regimens. Conclusions: the most frequently encountered histopathological patterns were humoral rejection, interstitial fibrosis and chronic cellular rejection. Patients under continuous treatment with cyclosporine developed chronic cellular reject more frequently; on the opposite, patients under continuous treatment with tacrolimus developed chronic humoral reject more frequently. **Keywords**: RENAL BIOPSY, ALLOGRAFT DYSFUNCTION, IMMUNOSUPPRESSIVE TREATMENT

The mechanisms responsible for the appearance of lesions in renal allograft are complex and include numerous multifactorial processes that are influenced by a variety of factors, both donor and recipient related, but also secondary to post-transplant events: ischemia-reperfusion injury, cellular and humoral immunity, viral and bacterian infections, or calcineurin inhibitors toxicity (1). For the diagnosis of allograft injury, clinical and paraclinical tests had been used, but the renal biopsy still remains „the golden standard" method (2).

The allograft biopsy is usually performed when cellular or humoral rejection is suspected. The main indicator for allograft dysfunction is represented by a rise in serum creatinine levels above the baseline values. One single abnormal value is not generally an indication, but on the other hand a rise of at least 25% above the baseline values represents an indication to perform such a biopsy (3).

Other signs of rejection, like inexplicable fever, edema, hypertension, eosinophilia, oliguria or anuria and proteinuria, are unable to predict this diagnosis in 30-50% of cases; as such histological confirmation is frequently necessary (4, 5, 6).

The aim of this study was to underline the importance of renal allograft biopsy (RAB) in the management of transplant pa-

tients from a single Renal Transplant Center.

MATERIAL AND METHODS

We analyzed all biopsies performed between in „Dr. C.I. Parhon" Dialysis and Transplantation Center, from 01.01.2007 to01.07.2012. A TRU-CUT 14 G needle and a BARD INSTRUMENTS biopsy pistol were used to perform RAB. All biopsy pieces were fixated in formaldehyde and later in paraffin. All sections had between 3 and 4 μm in thickness. We used HE, PAS and Masson Trichrome stain. For the interpretation of RAB the 2009 Banff Classification was used (7).

We also included in our analysis baseline demographic, clinical and therapy data of the patients, but also the evolution in renal function.

RESULTS

We included 23 biopsies from 20 patients that were from patients evaluated in our Transplant Centre.

A. General results

1. Age and sex – the age of patients was between 19 and 58 years (media 38.5 years);

2. The majority of biopsies were from young male patients (tab. I);

3. From the total of 20 patients, 17 had received the renal allograft from a living relative, while the rest from a cadaveric donor.

4. The median duration from the moment of transplantation till that of the biopsy was 7.05 years (between 1 and 15 years) (fig.1). The RAB was performed more frequently in patients with a transplant between 1 and 4 years.

5. Patients' co morbidities are presented in table II. Most patients had associated infectious and cardiovascular pathologies.

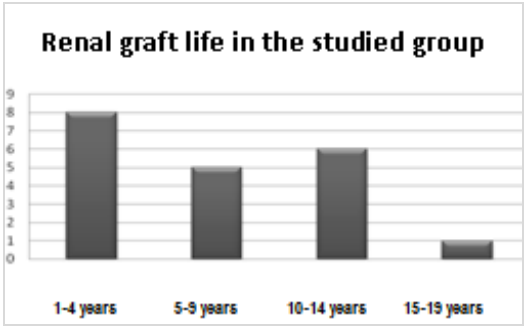

Fig. 1.The duration of renal transplant allografts.

TABLE I

The distribution of patients in regard with age and sex

		Number of patients	Number of biopsies
Sex	M	15 (75%)	18 (78.26%)
	F	5 (25%)	5 (21.73%)
Age intervals	15-24	3 (15%)	3 (15%)
	25-34	8 (40%)	10 (50%)
	35-44	6 (30%)	7 (35%)
	45-54	2 (10%)	2 (10%)
	55-64	1 (5%)	1 (5%)

TABLE II
Associated co morbidities

Associated pathology	Number of patients
HCV	**4**
VHB	1
CMV	13
PBKV	4
Hypertension	16

HCV – Hepatits C virus, HBV – Hepatits B virus, CMV - Citomegalovirus, PKBV – Polyoma BK virus.

4. **Pretransplant chronic kidney disease etiology –** in our study population the most frequent cause of CKD was chronic glomerulonephritis (12 patients); 3 patients had congenital renal abnormalities, while in the rest of patients the etiology was unknown.

5. **RAB indication –** six patients had a rapid rise in serum creatinine levels, the rest associating a more gradual decline in renal function with proteinuria > 1g/day.

B. Histopathological results

The most frequently histopathologies observed in our population were antibody mediated rejection (4 cases), interstitial fibrosis with tubular atrophy (3 cases) and T cell mediated rejection (3 cases) – see Table 3.

C. Post biopsy complications

Two patients had complications post RAB, and only case it was severe (subcapsular hematoma that later spontaneously remitted).

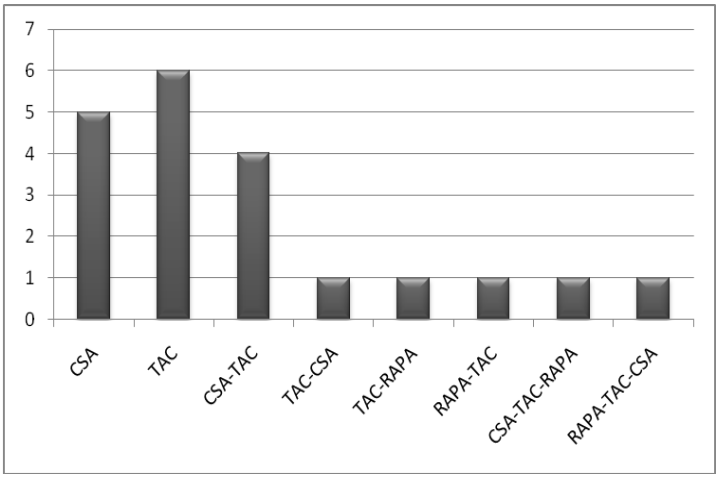

Fig. 2. Immunosuppression schemes in the study group:
CSA – Continuous therapy with Cyclosporine A. **TAC** – Continuous therapy with Tacrolimus. **CSA – TAC**: Cyclosporine – Tacrolimus switch. **TAC-CSA**: Tacrolimus – Cyclosporine switch. **TAC-RAPA**: Tacrolimus – Rapamycine switch.

D. Immunosupressive regimens

All regimens were based on three immunosupressives: prednison, myco-phenolate and either a calcineurin inhibitor (cyclosporine A (CSA) or tacrolimus (TAC)) or rapamycin (RAPA). The distribution of immunospressive regimens is presented in figure 2. In the observation period, most

patients remained on a calcineurin inhibitor (CSA or TAC) with a good evolution.

The modification of therapy was most frequently performed for chronic degradation of renal function (in the cases with CSA), diabetes (in the cases with TAC) or proteinuria (in the cases with RAPA).

Patients who had a CSA based regimen were more likely to develop chronic cellular rejection, while those with a TAC based regimen were more likely to develop chronic humoral rejection (tab. IV).

TABLE III
Histopathological results

Diagnostic	Number	Percentage (%)
Antibody mediated rejection	4	17.39 %
T cell mediated rejection	3	13.04 %
Interstitial fibrosis with tubular atrophy	3	13.04%
Non-diagnostic	3	13.04 %
Chronic allograft glomerulopathy	2	8.69 %
Borderline lesions	2	8.69 %
Virus infection	2	8.69 %
Chronic interstitial nephritis	2	8.69 %
Glomerulosclerosis	1	4.34 %
Calcineurin inhibitor toxicity	1	4.34 %

TABLE IV
Histopathological modifications according to the immunosupressive regimen

	CSA-TAC	TAC-CSA	TAC-RAPA	RAPA-TAC	CSA-TAC-RAPA	RAPA-TAC-CSA
T cell mediated rejection	**1**					
Interstitial fibrosis with tubular atrophy	**2**					
Borderline			**1**		**1**	
Calcineurin inhibitor toxicity	**1**					
Antibody mediated rejection	**1**					
Virus infection		**2**				
Chronic interstitial nephritis				**1**		**1**

DISCUSSION

The prevalence of end-stage chronic kidney disease is rising worldwide. At this moment there are 3 renal replacement therapies: peritoneal dialysis, hemodialysis and renal the quality of life and survival with the lowest long-term costs.

RAB represents the most sensitive instrument for detecting the cause of renal allograft dysfunction.

This paper underlines the significance of RAB for the management of a renal transplant patient. We retrospectively evaluated the histopathological results of all RAB performed in „Dr. C.I. Parhon" Dialysis and Transplantation Center in a five years period (01.01.2007 - 01.07.2012). There were only 23 biopsies from 20 patients.

The 4 cases with humoral rejection were diagnosticated at 1, 2, 7 months and 13 years after renal transplantation. After the treatment (all cases received 3 plasmapheresis, 2 patients also i.v. Imunoglobuline) there was amelioration in 3 cases. In the other case (the patient transplanted 13 years ago) there was an initial stabilization of serum creatinine levels, but he later returned to hemodyalisis.

In the three cases with cellular rejection, the evolution after methylprednisolone pulse therapy was favorable in all cases.

In the observation period, there was a 100% patient survival rate and a 95% renal allograft survival rate.

CONCLUSIONS

1. This study highlights the importance of RAB in the evaluation and management of renal transplant recipients.

2. RAB is of utmost importance in the clinical and therapeutical decisions, allowing medical practitioners to:

- identify and differentiate chronic or acute lesions in the allograft;
- initiate appropriate measures to stop or delay the progression to evident dysfunction and subsequent loss of the renal allograft.

3 . In our study the most frequent histopathological findings were antibody mediated rejection, followed by interstitial fibrosis with tubular atrophy and chronic cellular rejection;

4. Patients on continuous CSA treatment had a higher incidence of chronic cellular rejection, while those on continuous TAC treatment had a higher incidence of humoral rejection.

5. Post RAB complications have been rare, making this procedure a safe method of investigation kidney allograft dysfunction.

6. During the 5 years of the study, there was a 100% patient survival rate and a 95% renal allograft survival rate.

LEISHMANIASIS – AN UNUSUAL CAUSE OF SPLENOMEGALY IN ROMANIA

4. Department of Clinical Geriatrics

LEISHMANIASIS–AN UNUSUAL CAUSE OF SPLENOMEGALY IN ROMANIA (Abstract): Leishmaniasis is a parasitic infection caused by protozoans classified as *Leishmania* species. Romania is not considered an endemic country and there are only few reports of sporadic cases in the last 100 years. However, studies suggest that the disease is spreading north. We present the case of a 44 year old female that presented with asthenia, perspirations, vertigo, weight loss and menometrorhagias in small to medium quantity. Clinical exam revealed the presence of splenomegaly and her blood tests indicated she had pancitopenia; differential diagnosis included myeloproliferative or lymphoproliferative disorders, infections that evolve with spleen enlargement, autoimmune-related splenomegaly and hepatic - all tests were negative. She refused the bone marrow aspiration. Three months later, her condition worsened and the menometrorragias became more severe. Bone marrow aspiration revealed the presence of numerous intra and extracellular *Leishmania spp*. amastigotes. A detailed anamnesis showed that she had worked for six months in Italy as a care-giver nine months ago. She was transferred to Bucharest where she received optimal treatment. However, due to the continuous bleeding, the evolution was unfavourable. This is an alarm sign for physicians that should take into account the fact that, due to population migration and global warming, tropical infectious diseases are becoming more and more common. The signs and symptoms, as well as the treatment in leishmaniasis are reviewed, as well as a brief history of leishmaniasis in Romania. **Keywords**: VISCERAL LEISHMANIASIS, SPLENOMEGALY, TROPICAL DISEASES

Leishmaniasis is a parasitic infection caused by protozoans classified as *Leishmania* species, of the trypanosomatidae family. Transmission can occur after the bite of a phlebotomine sand fly (1) whose hosts are either animals (dogs or rodents), either humans, depending on geographical area (humans are more often hosts in hyperendemic areas).

The World Health Organization recognizes four forms of leishmaniasis, the occurrence of which depends on parasite

species and the reactivity of the immune system of the patient: cutaneous leishmaniasis (often self-healing and the most common form), diffuse cutaneous leishmaniasis (especially in immunocompromised patients), mucocutaneous leishmaniasis and visceral leishmaniasis (VL) (also known as "kala azar") - the most severe form, fatal if left untreated (2).

Over 90% of confirmed leishmaniasis infections are from India, Bangladesh, southern Sudan, Nepal and North-East Brazil (3); some Mediterranean countries such as Italy, Greece, Cyprus, France are considered endemic, as well as other European countries such as Portugal. Romania is not considered an endemic country and there are only few reports of sporadic cases in the last 100 years. However, studies suggest that the disease is spreading north because of several risk factors such as climate, population migration, (4) pet import (dogs as reservoir for the disease - leishmaniasis has up to 25% seroprevalence in domestic dogs in endemic countries) and adaptability of the vector to new environmental conditions (1, 2).

CASE REPORT

We present the case of a 44 year old female that was admitted to the Haematology department for asthenia, perspirations, vertigo, weight loss (7-8 kg in the last three months) and menometrorhagias in small to medium quantity. The bleeding had appeared one week prior to admission, whereas all the other symptoms had appeared three months ago. She had a history of uterine fibroma, diagnosed 9 years ago, and treated conservatively. She was a stay-at-home mother, did not smoke or drink, and she lived in a spacious rural household.

Clinical examination revealed only a massive splenomegaly (10 cm below the costal margin). She was pale and dehydrated but had no fever. Rectal examination showed no signs of active bleeding.

Differential diagnosis was centred on splenomegaly and included: 1. myeloproliferative or lymphoproliferative disorders (syndrome?); 2. infections that evolve with spleen enlargement (such as hepatitis, HIV, mononucleosis); 3. autoimmune-related splenomegaly (encountered in lupus and rheumatoid arthritis); 4. hepatic disorders (cirrhosis);

5. idiopathic splenomegaly (exclusion diagnosis).

Blood tests revealed the presence of pancitopenia, with hipochrome normocitary anaemia (Hb = 5,1 g/dl); her platelets were 50.000/mmc and white blood cell count was 1790/mmc, with a normal distribution and mature polymorphous lymphocytes that had morphological signs of activation (possibly due to a viral infection), thus eliminating myeloproliferative or lymphoproliferative disorders.

Echographic imaging confirmed the clinical suspicion of splenomegaly, with a 135 mm - spleen, but revealed no other pathological findings (echographically normal liver); hepatic tests (ALAT, ASAT) were within normal range, thus eliminating cirrhosis as a possible aetiology.

Markers for autoimmune diseases - rheumatoid factor, anti-cyclic citrullinated peptide antibodies, antinuclear antibodies and anti double-stranded DNA antibodies were negative, thus eliminating autoimmune-related splenomegaly. HIV testing, HbS antigen, anti-HCV antibodies, Cytomegalovirus antibodies and anti-toxoplasmosis antibodies were absent as well, with IgM, IgA and IgG values within normal limits, thus eliminating the most

common infections that evolve with spleen enlargement.

In order to further investigate the pancitopenia, other blood tests were performed: bilirubin (both fractions were only slightly increased) and reticulocyte count (increased); these results, correlated with the fact that the anaemia was mycrocitic, lead to the conclusion that the main mechanism by which it had appeared had been blood loss. Gynaecological consult confirmed the presence of a fibroma with no active bleeding at the time of the consult. Although the patients' stool tested positive for occult gastrointestinal bleed, both endoscopy and colonoscopy were negative for signs of active bleeding. Coagulation tests were performed - all within normal range. A bone marrow aspiration was suggested, but the patient refused the investigation.

The splenomegaly was considered to be reactive due to the presence of the activated lymphocytes in the formula. Leucopoenia and thrombocytopenia were interpreted in the context of a medullar aplasia. Anaemia was interpreted as having a mixed etiology - medullar aplasia, hypersplenism, menometrorhagias. The patient received blood transfusions and dietary supplements for the correction of anaemia. She was discharged with haematological parameters that had much improved, and she was prescribed dietary supplements (iron, folic acid, vitamin C).

Three-months follow-up examination revealed an increase in the dimensions of the spleen (175 mm), hepatomegaly and important gynaecological bleeding. Blood tests revealed the persistence of pancitopenia with a neutrophil count of 380 elements/mmc and elevated ferritin level. Due to her important bleeding, the patient was transferred to the Gynaecology department, where haemostatic uterine curettage was performed.

After surgery, she returned to the Haematology department. A bone marrow aspiration was suggested once more and this time the patient consented. The results showed the presence of numerous intra and extracellular *Leishmania spp.* amastigotes (fig. 1). A detailed anamnesis showed that she had worked for six months in Italy as a care-giver nine months ago.

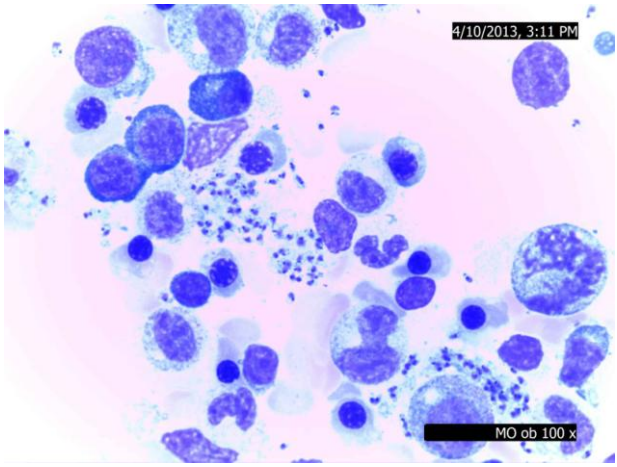

Fig. 1. Microscopic aspect of *Leishmania spp.* amastigotes from bone marrow aspiration

The patient was transferred to the "Victor Babes" Hospital of Infectious Diseases, where treatment with liposomal Amphotericin B was initiated. Metrorrhagia persisted (due to her uterine fibroma) and a second surgery was performed after which the bleeding continued; although best supportive care was given, the patient had an unfavourable outcome.

DISCUSSION

The purpose of this case presentation is to attract attention to the necessity of including tropical diseases in the differential diagnosis of difficult cases that do not respond to standard therapy. Considering the marked increase in population migration, the clinician must take into account imported infectious diseases. A meticulous anamnesis is essential in such situations, and it may help narrow the spectrum of etiological microorganisms and parasites, thus limiting the amount of tests required for a positive diagnosis.

Leishmania infection in Romania

The first report of a leishmaniasis case dates to 1912. No other cases were reported until 1954, when an outbreak of visceral leishmaniasis was reported in the Oltenia region. One other case was reported in 1991 (5). However, in the last 25 years, more and more leishmaniasis cases have been diagnosed in Romania - 14 cases of visceral leishmaniasis reported between 2000 and 2010. All patients had recently travelled to Mediterranean countries (6-8), as did our patient, who had travelled one year prior to her first hospital admission to Italy.

Signs and symptoms in VL

A descriptive study on 71 VL patients diagnosed in an African hospital indicated that the most frequent symptoms were fever, abdominal pain, loss of appetite, weight loss, epistaxis, diarrhoea, cough and joint pains (10). Similar rates are reported on an Italian population - all children and 90% of the adults were febrile at presentation (1).

Most common signs in VL include splenomegaly (60-97%), hepatomegaly (50-60%), lymphadenopathy (20%), ascites and lower limb oedema (around 10%) (1, 3, 10-11). The most common clinical presentation consists in fever associated with hepatosplenomegaly (1); some authors have identified a "classical triad" of signs, symptoms and laboratory findings in VL that consist in fever, splenomegaly and pancitopenia (9).

At admission, this classical triad was NOT present; the fact that our patient was afebrile at her first presentation augmented the difficulty of including leishmaniasis in the differential diagnosis; initially, there was no hepatomegaly (although it appeared at follow-up), no enlarged lymph nodes, no oedema and no bleeding other than the genital one interpreted in the context of the uterine fibroma. Laboratory findings were similar to other reported VL cases (12) - anaemia, leucopoenia with relative lymphocitosis and thrombocytopenia.

Delay in diagnosis in countries that are not endemic

VL is frequently misdiagnosed, especially in non-endemic countries and by physicians that have not had a lot of experience with tropical diseases. Diagnosis is difficult due to the unspecific early phase and the fact that the parasite is largely sequestered in the spleen, liver and bone marrow - traumatic interventions are required for a positive diagnosis (9).

For instance, Brazil is one of the coun-

tries that have experienced an increase in VL cases over the last two decades, with more and more areas becoming endemic for this disease. In the 1980's, in urban Brazil, there was an increase in VL mortality rates due to the fact that physicians underestimated and failed to diagnose VL - it was encountered only in certain rural areas at the time and they had little to no experience with this disease (13).

Our patient was correctly diagnosed approximately 14 weeks after her first hospital admission. This delay lead to an unfavourable prognosis and was a consequence of several factors: incomplete anamnesis, impossibility to perform bone marrow aspiration and the concomitant fibroma that complicated the case and aggravated the prognosis.

Particularities of the clinical case: young immunocompetent female (HIV negative, no immunosupressant medication); first anamnesis did not stress on her recent travels, so differential diagnosis did not include tropical diseases; first hospital admittance showed isolated splenomegaly (no associated hepatomegaly) and pancitopenia that could not be thoroughly investigated; associated fibroma as a source of continuous bleeding and confounder that lead to an unfavourable outcome.

CONCLUSIONS

This case report presents the management of a VL patient, with unfavourable outcome due not only to associated comorbidities, but also to delay in diagnosis and, consequently, treatment. Its purpose is to attract attention to the increase in incidence of this disease in particular and exotic diseases in general in non-endemic countries due to globalization and increasing migration; thus, they can no longer be excluded by Romanian physicians from the differential diagnosis. Such aetiologies should be suspected in patients that do not respond well to initial treatment, or that have travelled in the last three years to other countries.

ACKNOWLEDGEMENTS

We would like to thank Dr. Gabriela Marinescu for providing the microscopical images for this case. We would also like to thank Dr. Eduard Năstase and Dr. Tiberiu Gireadă for their medical opinion and feedback. Our thanks also goes to Professor Emanoil Ceauşu for providing information on her evolution in the Bucharest hospital.

NEWS

PERIODONTAL CHANGES IN PATIENTS UNDERGOING RADIOTHERAPY FOR HEAD AND NECK MALIGNANCY

The most common modalities used in head and neck cancer treatment are represented by surgical resection, radiotherapy and chemotherapy, used singly or in combination. Direct damage to the oral soft and hard tissue structures frequently occurs from radiotherapy and chemotherapy, and indirect damage may also arise from systemic toxicity. The prospective study conducted by a group of researchers from the department of Periodontics - Government Dental College, Calicut, India was designed to analyze the effect of radiotherapy on periodontal parameters in oncology patients prior to irradiation in the head and neck area, compared with 6 months following treatment. The statistical analysis was done using SPSS. The study sample consisted of 29 patients of head and neck malignancy (17 male and 12 female), of mean age 45.66 years. Only 22% of patients had various habits (eg. smoking, tobacco chewing, and alcohol consumption) and the majority of patients (27.59%) had tongue malignancy. All periodontal parameters represented by OHIS (the oral hygiene index Siller), CAL (clinical attachment level), GR (gingival recession), except PPD (probing pocket depth) were significantly increased after radiotherapy. When comparison was made between doses and fractions, only in mandible statistically significant difference were observed in gingival recession.Although there was no significant change probing pocket depth, there was increased gingival recession, clinical attachment level, and plaque index associated with radiotherapy. In this study, 61.5% cases of mandibular teeth and 34.4% cases of maxillary teeth showed attachment loss greater than 0.2 mm. In conclusion, all patients with head and neck malignancy should undergo an oral examination before the initiation of cancer therapy with adequate prophylaxis. THE EFFECT OF PIOGLITAZONE ON NON-PREGNANT FEMALE GENITAL TRACT IN EXPERIMENTAL DIABETES MELLITUS (Abstract) **Aim**: The effects of pioglitazone, a very used drug in the treatment of non-insulin dependent diabetes mellitus, were tested at the level of ovary of non-pregnant female rats. **Material and methods**: The experiment was performed on three groups of adult non-pregnant female rats. **group 1** was a control group (and did not receive any substance), **group 2** received streptozotocin 60mg/kg i.p. (single administration), and **group 3** received streptozotocin 60 mg/kg i.p. (single administration) and pioglitazone 5 mg/kg/day p.o., daily for 8 weeks. The plasma glucose, cholesterol and triglyceride levels were determined before drugs administration and during the experiment. After 8 weeks the animals were anesthetized and sacrificed. The ovaries were examined by optical microscopy. A morphometric evaluation was performed. The obtained data were statistically interpreted by ANOVA test. **Results**: After 8 weeks of treatment the plasma glucose and triglyceride levels were significantly lower in the pioglitazone treated group compared to the streptozotocin only group. In the pioglitazone group the number of primordial and primary ovarian follicles was significantly higher than in streptozotocin only group. **Conclusions**: The results showed a partial protective action of pioglitazone on ovary in non-pregnant diabetic female rats. **Keywords**: DIABETES MELLITUS, STREPTOZOTOCIN, PIOGLITAZONE, OVARY

Diabetes mellitus (DM) is one of the most important diseases in human clinic. It affects all body tissues but unequally. In the therapy of non-insulin dependent diabetes mellitus (NIDDM) a significant number of oral antidiabetic agents with different chemical structures and mechanisms of action are used. One of the major classes of antidiabetic drugs is the thiazolidinedione group.

Thiazolidinediones (such as rosiglitazone and pioglitazone) are peroxisome proliferator-activated receptor-γ (PPARγ) agonists and are used to improve insulin sensitivity in DM patients. Thiazolidinediones are drugs that reduce the plasma glucose level, haemoglobin A_1c level and enhance tissue insulin sensitivity (1). There are many data on how diabetes mellitus affects the female reproductive organs but much less information on DM influence on non-pregnant female genital tract. The aim of this study was to highlight the action of pioglitazone on ovaries in non-pregnant female rats with experimentally induced diabetes.

MATERIAL AND METHODS

We worked on three groups of eight adult non-pregnant female Wistar rats each (eight weeks old, weighing 170-250 g) bred in normal laboratory conditions. The animals were housed in polycarbonate cages, at a temperature of 22±2°C. During the study the animals were fed with a commercial granular diet and water *ad libidum*. DM was induced in overnight fasted rats by a single intraperitoneal administration of 60 mg/kg streptozotocin (STZ) (Sigma®) dissolved in citrate buffer.

Group 1 of female rats was the control group and did not receive any substance.

Group 2 of female rats received STZ 60 mg/kg i.p.

Group 3 of female rats received STZ 60 mg/kg i.p. and pioglitazone 5 mg/kg/day p.o., daily for 8 weeks.

After 8 weeks all animals were anaesthetized and killed by decapitation and the ovaries were removed and examined by optic microscopy. Plasma glucose, cholesterol and triglyceride levels were determined at baseline (before STZ administration) and after 8 weeks of treatment in each group. The obtained data were statisticaly interpreted by ANOVA test. Morphometric analysis was performed on scanned images of histologic samples, using Zeiss Observer Z1, Tissue Gnostics 9, Tissue Faks system. The aquisited images were analysed in order to determine the most representative fields; all the investigated parameters were identified in selected fields of view (FOV) from each distinct region of the resulted images.

The study protocol was approved by the Ethics Committee of the Iasi "Grigore. T Popa" University of Medicine and Pharmacy. All animal procedures were performed according to the European Union law on the "Care and Use of Animals for Scientific Purposes" and in accordance with the "Recommendations of the Declaration of Helsinki".

RESULTS

After 8 weeks of treatment the plasma glucose and triglyceride levels were significantly lower in the pioglitazone group compared to STZ only group (mean plasma glucose levels of 203.83±14.61 mg/dl in pioglitazone group vs. 352.17±38.79 mg/dl in STZ group, and mean triglyceride levels of 191.3±12.04 mg/dl in pioglitazone group vs. 261.2±9.52 mg/dl in STZ group, $p<0.05$). The mean cholesterol level was 93.83±7 mg/dl in STZ group compared to 80±7.51 in pioglitazone treated female rats. In pioglitazone group the number of primordial and primary ovarian follicles was significantly higher than in STZ only group ($p<0.05$).

DISCUSSION

DM is associated with diabetic impairment of female reproductive function and the reduction of fertility (2). The STZ-induced diabetes mellitus is a classical model for experimental diabetes. Streptozotocin (60 mg/kg) is a substance known to destroy only a part of beta pancreatic cells (about 60% of all beta pancreatic cells). The plasma insulin level significantly decreased but with the preservation of an important mass of functionally beta cells (3, 4). After STZ administration the rat pancreas produces about 25-30% of the initial insulin secretion. The STZ-induced diabetes is characterized by the increase in the levels of fasting plasma glucose, lipid peroxidative products and a significant decrease of antioxidant enzymes (superoxide dismutase (SOD), catalase, glutathione peroxidase and non-enzymatic antioxidants (reduced glutathione) (5).

Thiazolidinediones have been extensively used as insulin-sensitizers in the treatment of NIDDM. Activation of PPARγ by this group of drugs leads to a lot of metabolic and anti-inflammatory effects (6).

PPAR-γ is a member of the nuclear hormone receptor super-family. Pioglitazone, a specific agonist for PPAR-γ, was implicated in the control of inflammatory processes and the modulation of various cytokines expression. PPAR-*γ* agonists inhibit the synthesis of pro-inflammatory cytokines, such as TNF-*a* and IL-*6 (*involved in the failure of female reproductive activity) (7), diminish the oxidative stress (8) and inhibit or prevent cell apoptosis. Pioglitazone also reduces the pro-inflammatory cytokines IL-6 and IL-8 synthesis in endometrial stromal cells by a PPAR-γ-independent mechanism (9) and has a favourable effect in NIDDM, decreasing the incidence and severity of some complications. This drug also showed

a protective effect in retinal ischemia/reperfusion injury in rats (10).

Suppression of IL-1β could be another mechanism in pioglitazone-induced protective effect on ovary and uterus in STZ diabetic rats (11).

In our study, the effects of pioglitazone on non-pregnant rat ovary were different in different follicle types. The protective effect was stronger in the primordial follicles. The results were obtained with pioglitazone doses usually used in rat experimental tests (3-20 mg/kg/day) (12, 13). There were not observed influences on genital female system and fertility in normal animals after long time (8 months) of pioglitazone administration (14)

The obtained data are in agreement with the results of other authors which observed a partial protective effect of pioglitazone in experimentally-induced gastric ulcer (11), streptozotocin-induced diabetic nephropathy (13, 15) and experimentally-induced liver fibrosis in rat (16). Besides increasing sensitivity to insulin, pioglitazone increases tissue glucose utilization and decreases the synthesis of glucose from the liver (17). Pioglitazone also exerts a protective effect on β-cell function. Thiazolidinediones promote beta-cell survival and regranulation as well as maintenance of beta-cell mass (18). In addition to its beneficial effects on glucose homeostasis, pioglitazone exerts a number of other pleiotropic effects. This drug reduces blood pressure, improves endothelial dysfunction, corrects diabetic dyslipidemia and decreases the circulating levels of inflammatory cytokines and others (19). PPAR γ agonist pioglitazone used to treat NIDDM has also been demonstrated to be an effective antioxidant substance in oxidative stress in the animal models (20). Pioglitazone improves adipose tissue and liver insulin sensitivity and increases insulin-stimulated inhibition of lipid oxidation (21).

The obtained data show that pioglitazone significantly reduces the number of atretic ovarian follicles in STZ diabetes and increases survival of the ovarian primordial follicles.

Our results are in agreement with data indicating that pioglitazone treatment in polycystic ovary syndrome is associated with improvements in insulin action and glucose homeostasis and ameliorated the hyperandrogenic ovarian response. The granulosa cell responsiveness to FSH was enhanced by insulin after improved insulin sensitivity induced by pioglitazone (22). This drug ameliorated endothelial dysfunction of NIDDM patients. Increased nitric oxide production could be associated with a protective action and with the improvement of endothelial dysfunction.

CONCLUSIONS

This study showed that in STZ-induced DM in non-pregnant rats, the treatment with pioglitazone increased the number of primordial and primary ovarian follicles and reduced the number of atretic follicles.

METABOLIC SYNDROME: PARTICULARITIES IN OVERWEIGHT WOMEN WITH POLYCYSTIC OVARY SYNDROME AS COMPARED WITH OBESE WOMEN WITHOUT OVARIAN DYSFUNCTION? (Abstract): **Objective.** The study assesses the frequency of metabolic changes in overweight patients with or without polycystic ovary syndrome. **Material and methods**: The study group was made up by 148 patients of whom 99 patients without polycystic ovary syndrome (group A, control group) and 49 with polycystic ovary syndrome (group B), that came in our endocrine unit for a weight loss program, in the September 2008 - March 2009 period. Morphometric parameters (height, weight, body mass index), biological parameters (cholesterol, triglycerides, blood glucose, glycated hemoglobin) and body composition analysis by measuring the electrical bioimpedance, were evaluated. **Results:** Patients with polycystic ovary syndrome have a higher percentage of total fat (38.22±7.2) than patients without polycystic ovary syndrome (36.316±5.65) ($p<0.05$), for the same characteristics. Glycated hemoglobin, blood glucose and triglycerides were found higher in group B patients. Furthermore, the amount of free testosterone is higher in group B patients compared to those in group A. The prevalence of metabolic syndrome was higher in polycystic ovary syndrome cases (26.13%) comparative with overweight cases (16.16%, $p<0.01$). **Conclusions:** In the group of overweight patients, the group of patients with polycystic ovary syndrome is a particular group showing more severe metabolic changes. **Keywords**: OVERWEIGHT, POLYCYSTIC OVARY SYNDROME, METABOLIC SYNDROME.

The polycystic ovary syndrome (PCOS) is the most common endocrine disorder that affects the female population of reproductive age. Its incidence is variable, ranging from 4% (1), 7.1% (2) to 33% (3), depending on the working group, ethnic group (4,5) or definition criteria for metabolic syndrome. (3). There are many diagnostic criteria; generally the presence of oligo-ovulation or anovulation, the clinical and/or biochemical signs of hyperandrogenism are considered, excluding other diseases: Cushing's syndrome, 21 hydroxylase deficiency, other forms of congenital adrenal hyperplasia, hypothyroidism, androgen secreting tumors (4, 5). Highlighting the morphology of the polycystic type is not compulsory; on the contrary, 8-25% of healthy women and 14%

of those under contraceptive therapy show the typical ultrasound appearance (6). Overweight and peripheral insulin resistance is common issues encountered in this syndrome (2). The metabolic syndrome (MeTS) can be considered as part of the PCOS, in the vast majority of cases (7). Obesity and insulin resistance are closely linked to the initiation and maintenance of hyperandrogenemia (2, 8). Obesity, especially the abdominal one, may play a pathogenetic role in the development of PCOS (9) favoring excess androgen synthesis.

Hyperandrogenemia *per se* favors visceral obesity (10) in its turn. However, not all overweight women have changes in the ovaries; respectively not all the patients having PCOS are obese.

The core of PCOS is a MeTS. This is the difference between simple ovarian cysts and PCOS, respectively the metabolic implication, cardiovascular and diabetic long-term risk, for this particular group of young females. Moreover, if not only the presence of MeTS, but also the severity of the metabolic impairment, as considered the number of altered metabolic parameters is considered, differs in overweight females with PCOS, the implications regarding cardiovascular risk are more important than we think.

Data on potential metabolic-hormonal differences between obese patients with or without PCOS are relatively few.

This study aims to evaluate mainly the metabolic and hormonal profile of obese patients, with or without the diagnosis of PCOS in order to develop an innovative method and integrating support in diagnosis assistance.

MATERIAL AND METHODS

The study group was recruited from patients who resorted of the Clinic of Obstetric Gynecology I and III, Timisoara, in the endocrine ambulatory, between September 2008 and March 2009. All the cases were self-addressed for establishing a weight loss program by our endocrinologist, because her results in the field of weight loss and life style changes. They were with no pre-diagnosed ovarian dysfunction or other endocrine diseases. All the patients entitled themselves as "healthy but overweight".

Out of the total of 227 women who came for assessment in order to establish a nutrition program, 20 cases were of normal weight, 59 subjects met one of the exclusion criteria, and 148 patients remained to form the actual study group. Their age was between 16 and 40, the mean age being 29.35±6.225, their weight was between 54 and 124.9 kg, the mean weight being 90.76±15.24 kg, and their body mass index (BMI) was 31.50±5.18 kg/m^2, ranging between 25.4 and 46.9 kg/m^2. Of the total of 148 overweight women, 99 women were considered as the control group (group A) and 49 women had the general characteristics of the PCOS (group B). The general characteristics of the two study groups are presented in table I.

- **Inclusion criteria:** Young females address by themselves to the endocrine unit of our Clinic, starting September 2008 to March 2009, with overweight weight exceeding the ideal weight for one's age (BMI>25 kg/m^2), age below 40, with not known endocrine disease.

- **Exclusion criteria:** male patients, hypothyroidism (37), 21-hydroxylase deficiency (5 non-classical form/late-onset), primary hypercortisolemia (1 case), functional hyperprolactinemia (15 cases), precocious ovarian failure –premature menopause (0 cases), diabetes mellitus, hyper-

tension, normal weight (BMI < 25 kg/m^2) and morbid obesity (BMI>45 kg/m^2).

All patients completed a comprehensive assessment protocol:

- **Anthropometric assessment:** height (without shoes) by means of a stadimeter (Tanita), weight (without clothes), and BMI calculation. Abdominal circumference was measured with a tape 1 cm wide, as the minimum circumference between the iliac crest and rib side edges, respectively hip circumference as the maximum circumference of the hips.

Body composition was determined by means of an analyzer of electrical bioimpedance, Tanita BC-418, Tanita Corp. Japan, with evaluation of composition of each segment and determining the basal metabolic rate. The general and segmental composition of trunk, upper and lower limbs was assessed for each patient;

- **Assessment of menstrual disorders:** cycles longer than 45 days, or less than 8 cycles per year, respectively secondary amenorrhea, inter-menstrual bleeding, menstrual flow changes: longer than six days or less than 2 days;

- **Hirsutism:** Ferriman Gallwey score values greater than 6;

- **Metabolic Assessment:** determining blood glucose, high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL-C), triglycerides (Tg), glycated hemoglobin, uric acid;

- **Hormonal profile:** free testosterone, 5-dehydroepiandrosterone sulphate, androstenedione, luteinizing hormone/ follicle stimulating hormone ratio, 17 hydroxyprogesterone, thyroide stimulating hormone, prolactin, plasma cortisol;

- **Diagnostic criteria used:**

1. hypothyroidism: thyroid stimulating hormone greater than 4 IU/L, with or without symptoms or obvious clinical signs;

2. primary hypercorticism: elevated plasma cortisol values, insuppressible with nocturnal inhibition with 1 mg dexamethasone;

3. 21-hydroxylase deficiency: increased levels of 17-hydroxyprogesterone, positive response to stimulation with 100 mg adrenocorticotropic hormone;

4. PCOS (Rotterdam 2003 criteria): anovulation/menstrual disorders, hyperandrogenemia: Ferriman-Gallwey score over 8, elevated free testosterone values >0.011 nM/L, 5-dehydro-epiandrosterone sulphate above the age appropriate limit, polycystic ovary morphology in ultrasound images;

5. MeTS (at least three criteria): waist circumference ≥80 cm, hypertension ≥130/85 mmHg or antihypertensive therapy, hypertriglyceridaemia, Tg ≥150 mg/dL, hypercholesterolemia, HDL-C <50 mg/dL;

STATISTICAL ANALYSIS

T-student test was performed with the NCSS 2007 software.

RESULTS

a. Mean weight, BMI and total body fat in obese patients with or without PCOS

The mean weight of patients who have PCOS is higher as compared to that of patients without ovarian involvement, but does not reach the threshold of statistical significance. In contrast, BMI is significantly higher in women with PCOS ($p<0.015$) (fig. 1). The difference is emphasized when body composition is assessed, the adipose tissue being significantly better represented in the case of PCOS. The differences are not due to differences in size, weight or fluid com-

partment (tab. I).

The percent of total body fat is significantly higher in B group (38.22±7.20 %) than in control (36.31±5.65 %), p<0.06. When we evaluated each section, the statistical significance was observed only in the upper half of the body (values measured in % of fat):

- Right hand: 40.64±9.27 vs. 38.43±7.85, p<0.05;
- Left hand: 40.64±8.77 vs. 37.98±7.47, p<0.04;
- Trunk: 35.102±8.53 vs. 33.63±6.8, p<0.008.

TABLE I

General characteristics of the two study groups

	Group A (without PCOS)			**Group B (with PCOS)**			**p**
Parameter	Mean±SD	Min	Max	Average SD	Min	Max	
Age (years)	29.9±6.40	18	40	28.41±5.55	16	40	0.916
Height (cm)	165.79±5.94	144.4	180	164.02±5.96	154	182	0.092
Weight (kg)	79.41±1.41	75.5	124.9	82.57±1.73	54	124.3	0.060
BMI (kg/m^2)	28.84±4.97	27.5	46.9	30.93±5.398	25.4	44	0.011

Even the fat mass was higher at the inferior limbs, the difference was not statistically significant (40.31±6.77 vs. 39.23± 5.56, p=0.1658 right side, 40.91±9.27 vs. 39.23±5.56, p=0.1561 left side).

The same bioimpedance evaluation is measuring the basal metabolic rate (BMR). When considering that besides genetic type, age, sex, height and weight are the principal determinants of BMR, we could expect the PCOS group should have higher BMR. But this was not the case: 1544.57±178.284 (group A) vs. 1574.67± 201.603 (group B), p=0.1798.

b. The degreee of weight excess in overweight patients with or without PCOS

Because overweight was an inclusion criteria, we could observe differences only in the prevalence of obesity between the two groups. When we looked at the pool of patients, we observed that the presence of obesity *per se* (67.35% vs. 51.52%) but also the severity of the disease was higher in PCOS cases: moderate obesity 29.40 vs. 12.12%, severe obesity 12.24% vs. 9.09% respectively (tab. II).

The same significant difference was observed also at the level of circumferences, as a surrogate marker for overweight (tab. III).

TABLE II

Severity of overweight in absolute values and percentages in the two study groups.

Severity of overweight	**Overweight**	**Degree of obesity**		
		I	**II**	**III**
Group B (with PCOS)	16 (32.65%)	17 (34.69%)	10 (29.40%)	6 (12.24%)
Group A (without PCOS)	48 (48.48%)	30 (30.30%)	12 (12.12%)	9 (9.09%)

TABLE III
Circumferences specific for assessment of metabolic involvement in the two study groups.

Circumference	Testifier (Group A)	PCOS (Group B)	Significance threshold
Abdominal (cm)	98±5	99±6	p<0.05
Hips (cm)	116±6	118±7	p<0.05
Waist/hips ratio	0.84±0.06	0.87±0.009	p<0.02

c. Metabolic imbalances in overweigt females with or without PCOS

Differences between the two groups are apparent not only in morphometry, body composition and degree of obesity but also from the metabolic point of view.

Patients with PCOS have significant higher values of glycated hemoglobin (p=0.035 vs. p<0.04), glicemia (p=0.009 vs. p<0.001) and Tg (p=0.029 vs. p<0.02), compared with cases without PCOS. The other metabolic parameters, HDL-C, LDL-C, and uric acid were higher in PCOS group, even though the difference did not met a level of significance (p=0.661 vs. p=0.546).

The metabolic assessment of the two groups of patients shows a high incidence of metabolic complications. Each metabolic component is modified to a greater extent in case of combination with the MeTS: HgA1c increased in 18/49 cases, HDL-C decreased in 28/49 cases, LDL-C increased in 9/49 cases and Tg in 20/49 cases (fig. 1).

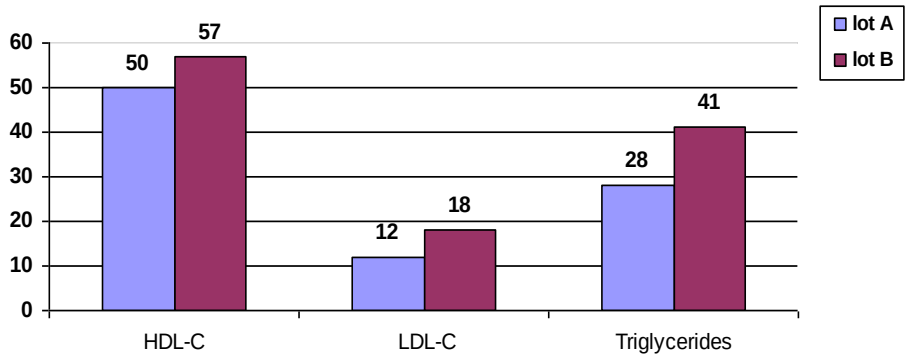

Fig. 1. Prevalence of isolated metabolic changes in the two groups with PCOS (group B) and without PCOS (group A).

The ordinate represents the percentage of patients with abnormal metabolic parameters.

d. The presence of metabolic changes, defined as the presence of increased 2, 3 or 4 metabolic components besides increased waist circumference, as a minimum criteria of MeTS in obese patients with or without PCOS

The overall prevalence of MeTS is

19.59%. There are significant differences between the prevalence of MeTS in the group of the overweight patients without PCOS (16.16%) (Group A) and in combination with this syndrome (26.53%, $p<0.01$) (group B).

The differences are great, no matter if considering the presence of two, three or even four criteria defining MeTS (fig. 2). If we consider the number of metabolic changes as a severity of the metabolic disbalance

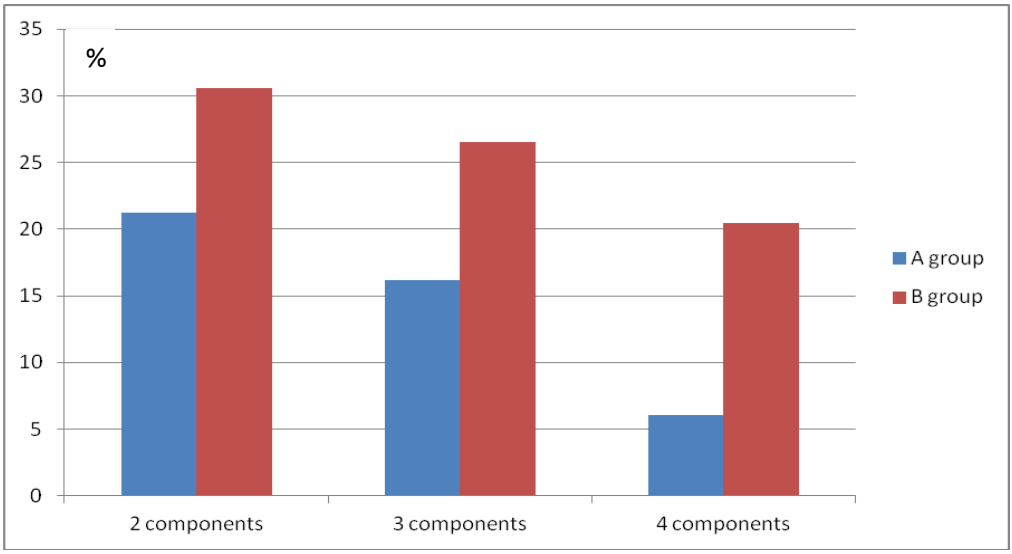

Fig. 2. Prevalence of MeTS in the groups of patients with PCOS (group B) and without PCOS (group A).

The ordinate represents the percentage of cases presenting 2, 3 and respectively 4 metabolic components defining MeTS besides increased waist circumference

e. Hiperandrogenemia in cases with or without PCOS

Clearly, not only overweight determines the presence of MeTS, but also the typical hormonal constellation, hyperandrogenemia. Of course, the mean values of all androgenic hormones were higher in cases of group B, as compared with control group, because hyperadrogenemia is a criteria for PCOS diagnostic. In the same overweight group, the hyperandrogenic patients have significantly higher metabolic complications. The estimated relative risk (ERR) of having MeTS in the presence of PCOS is 1.873, nearly four times higher compared with the ERR in the absence of PCOS. In case of overweight combined with hyperandrogenemia, the relative risk (RR) of developing MeTS is threefold as compared to the one generated by isolated overweight (RR 0.3265 vs. 0.1313, $p<0.02$) (tab. IV).

The coefficient of correlation between the severity of hyperandrogenemia (expressed by the values of free testosterone) and metabolic parameters is poor (tab. V).

Analyzing the prevalence of MeTS in the group of patients with PCOS (group B) we have identified differences between the level of hyperandrogenemia in the presence or absence of the MeTS (tab. VI).

TABLE IV

Metabolic parameters assessed in the two groups.

Parameter		Average	DS	ES	95% LCL	95% UCL	T	p
Glycated Hg	A	5.436	3.1383	0.313	4.814	6.059	-1.8184	0.035

DHEAS µg/dL	414.29±63.37	444±58.116	0.5530	0.291

DISCUSSION

The purpose of this study was to evaluate the presence and severity of MeTS in young, overweight women with PCOS. We defined a control group made up by patients whose weight was over the ideal weight for their age, who did not meet the diagnostic criteria of ovarian involvement of the hyperandrogenic type. Under the same conditions of height, weight, age and BMI, the prevalence of metabolic involvement is much higher in subjects with PCOS.

The relatively high prevalence (25.6%) of MeTS falls within the limits described in literature (11, 12). But there are studies that

show a lower incidence of only 5 to 10% (13). Yet diagnostic criteria of MeTS often vary, low-prevalence studies (13) have the same incidence of about 20% (22.7%) when there are 2 metabolic changes and also an increased waist circumference. Even without the criteria for MeTS, the prevalence of metabolic problems was high (50-55%), as described in the literature (4). Also the use of adult, respectively adolescent criteria generates differences (11). We can consider that the presence of PCOS increases the prevalence of MeTS (11, 12, 14). In our case the estimated RR of MeTS in the presence of PCOS was four times higher, similarly to other studies (12). The most frequent components of MeTS were increased waist circumference and LDL-C associated with peripheral insulin resistance (11, 12, 14).

As we saw from the data of Table II, not only the prevalence but also the severity of metabolic imbalance are higher in cases of associated PCOS: basic hyperglycemia as well as hypertriglyceridemia are significantly higher (12, 13). Even if hyperandrogenemia is considered the key to this syndrome (8, 9) we have not noticed the described important direct correlations with free testosterone, total or free fraction and the degree of imbalanced metabolic parameters (13, 15). However, the PCOS cases with MeTS had higher androgen levels as compared with non-MeTS PCOS cases (tab.VI) (15, 16). Levels of correlations were low and did not reach the statistical significance threshold (tab.III). However there are significant differences between the levels of hyperandrogenemia in patients with PCOS with or without metabolic complications (tab.V).

Generally hyperandrogenemia and increased waist circumference have the most significant associations with the incidence of MeTS, respectively peripheral resistance to insulin.

The present paper brings the metabolic component of the PCOS forward. Considering that in daily medical practice there is a large overlap between polycystic ovary morphology, secondary to anovulatory cycles, and PCOS diagnosed without assessing hyperandrogenemia and/or metabolic implications, it is imperative for us to warn our colleagues regarding the differences in pathology as well, besides the differences in nomenclature.

To our knowledge, this is the first study in our country, which overweight assessment includes measuring of the presence and distribution of adipose tissue by determining electrical bioimpedance of tissues. Higher abdominal fat content are associated with the presence of PCOS and MeTS as compared with control group, as abdominal fat and obesity related hyperinsulinemia favors hyperandrogenism (9).

Developing an innovative method and integrating support in diagnosis assistance for all the patients from the study would facilitate collaboration on a multicenter and multispecialty level, thus allowing the assessment of a greater number of cases and the participation of more physicians in the diagnosis and therapy procedure.

CONCLUSIONS

1. PCOS is associated with high incidence of MeTS as compared with aged matched controls.

2. The severity of metabolic imbalance (assessed by percent of changes and also degree of variance from the upper normal range) is more important in overweight PCOS cases, as compared with overweight age matched controls.

2. In a case of excess weight and multicystic ovarian morphology on ultrasound, investigation of hyperandrogenemia and metabolic components is important for identifying the moderate and long-term risk group for cardiometabolic disease.

3. Excess adipose tissue in cases of PCOS association with overweight is higher than in cases of overweight without ovarian complications, both in general and in the abdominal perivisceral area in particular.

3. Discipline of Family Medicine

OSTEOPOROSIS IN RHEUMATOID ARTHRITIS (Abstract): Osteoporosis (OP) is a disease of great medical and social importance and it is reported frequently and precociously in rheumatoid arthritis (RA) patients. **Material and methods**: A retrospective study was conducted on a random sample of 180 patients admitted in the period 2011-2012 to the Rheumatology Clinic of the Iasi Rehabilitation Hospital. The patients were diagnosed with RA and osteoporosis and some clinical and biological parameters were analyzed. Patients were divided into two groups for a comparative study: group I – seropositive = 115 cases (63.89%); group II – seronegative = 65 cases (36.11%). **Results and discussion**: The 180 patients diagnosed with RA and osteoporoses were randomized into other two groups. The serum rheumatoid factor (RF) in RA and osteoporosis patients was determined by Latex and Waaler Rose reaction. The radiological examination showed that 23.47% of patients in group I and 9.23% of patients in group II have experienced at least one fracture. DXA (*Dual X-Ray Absorptiometry*) testing showed a value of <-3.5 in group I (13,04%) and in group II (9.23%), these results indicating a high risk of fracture, particularly in group I (seropositive). **Conclusions**: The results confirm that RA patients are at increased risk of osteoporosis, and the additional risk of disability and serious socioeconomic implications negatively affect the prevention and development of the disease. **Keywords**: RHEUMATOID ARTHRITIS, OSTEOPOROSIS, CHRONIC INFLAMMATION, BONE MINERAL DENSITY.

Rheumatoid arthritis (RA) is a disease with high risk of osteoporosis, resulting from the association of several factors: bone mass loss (characteristic to RA development) by the risk conferred by the disease itself (inflammatory mechanisms with activation of various cytokines and alteration in the RANKL/OPG balance, prolonged immobilization, effects of corticosteroid therapy and other therapeutic agents), the predominance of female population (which implies an increased risk of bone mass loss caused by the occurrence of postmenopausal osteoporosis), and the increased life expectancy, that leads to an increase in the number of elderly persons who are also at increased risk of decline in bone mass (1,3,4).

The study aims to assess the prevalence of osteoporosis (OP) in RA patients, to establish the relationship between OP and clinical, biological and therapeutic variables, and to identify the risk factors that contribute to the decrease in bone mineral density in order to assess the bone tissue affected by disease and treatment.

MATERIAL AND METHODS

One hundred and eighty patients were surveyed for RA and OP in the period 2011-2012 in the Rheumatology Clinic of the Iasi Rehabilitation Hospital. The patients were divided into two groups for a comparative study: group I included seropositive patients (115:63.89%) and group II included seronegative patients (65:36.11%). The patients in the two groups did not differ significantly in age, average age at onset, sex distribution, and disease severity. There have been two studies:

A. *Epidemiological* study – aimed to investigate the effects of the disease and to determine if correlations can be made with environmental factors involved in the onset and development of the disease;
B. *Clinical* study - aimed to measure bone mineral density in patients diagnosed with RA in order to assess bone tissue.

ACR criteria (1987) were used in the diagnosis of RA, and the diagnosis of OP was made by osteodensitometry with dual beam X-ray using Hologic densitometer.

RESULTS AND DISCUSSION

A. Epidemiological study – the sex ratio was consistent across the two groups (χ^2=0.02; GL=1; p=0.889), with odds ratio of 1.05 (OR=1.05; IC95%: 0.52÷2.11).

The *age* and *sex* distribution of patients showed the predominance of the female sex, which accounted for 95.65% in the first group and 100% in the second group.

Age distribution revealed that the incidence of disease increases from the fourth decade of life onwards, especially in group II (χ^2=24.62; GL=5; p=0.0002) (fig.1, 2).

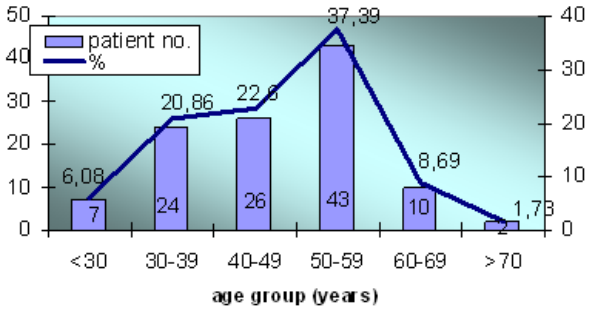

Fig. 1. Age distribution in group I of seropositive patients

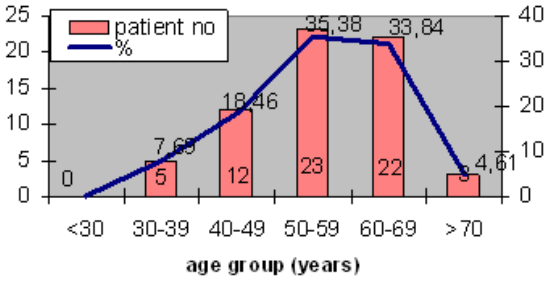

Fig. 2. Age distribution in group II of seronegative patients

The investigation of rural-urban differences showed that most patients lived in urban areas, 62% urban and 38% rural patients.

The analysis of educational level showed that 72% of the patients had primary education, 26% secondary education and 2% higher education. The average time between disease onset and diagnosis was 2.2 years, with significant differences. This also correlated with the severity of disability, showing that early diagnosis and appropriate treatment during the onset stage lead to good outcomes and maintenance of work ability (tab. I).

TABLE I
Duration of rheumatoid arthritis

CASES	NUMBER OF PATIENTS	AGE AT DISEASE ONSET	DURATION OF RHEUMATOID ARTHRITIS
Group 1	115	40± 15(years)	12 ± 5(years)
Group 2	65	40 ± 5	5 ± 5
Statistical significance		p>0.05	p<0.001

In the study groups the onset of RA was earlier in the seropositive as compared to the seronegative patients, with a peak in the fourth decade of life.

A psychological examination was conducted in 50 patients for a psychological profile of RA patients. One of the dominant negative affective states was pain, expressed as a particular, unpleasant feeling, accompanied by a number of reflex somatic and vegetative phenomena with a negative psychological connotation, because pain was caused by the body but affected the psyche, and it was more or less accepted. The onset of pain leads to a series of psychological changes that provide a certain experience of the disease. This is especially the case for chronic diseases, such as RA (4,8). Failure of treatment or the natural course of the disease associated with painful symptoms can lead to anxiety and depression with a poor prognosis. Knowing the individual psychological characteristics of RA patients plays an important role in the therapeutic approach because a good therapy includes also the emotional and affective aspects (2, 7).

B. Clinical Study

DXA osteodensitometry allows the early assessment of the degree of decreased bone density and the early diagnosis of osteopenia or osteoporosis, based on scores that suggest a different therapeutic approach (5, 6, 7).

The T score expresses the difference between the measured value and the reference value in control population. The Z score compares bone density in the patient with that of an age-matched person in order to assess the degree of bone loss. A negative Z score means that the patient has brittle bones, and a positive Z score means normal ranges. According to test results, the doctor may prescribe a medication that maintains or restores the skeletal system and recommend regular exercise and an adequate intake of calcium and vitamin D. DXA technology is also effective in monitoring the effects of OP treatment and in diagnosing other diseases that cause bone loss (2, 3, 6).

Morning stiffness was one of the main symptoms that made patients to see a doctor. It lasted significantly longer in group II

(χ^2=9,79; GL=1; p=0,007). In group I patients, 43.5% compared with 23.1% in group II, had morning stiffness lasting 15-30 minutes, while a duration of 30-60 minutes was observed in 41.7% of the patients in group I and 55.4% in group II. Morning stiffness lasting over 60 minutes was recorded in 21.5% of patients in group II and only in 10.4% of patients in group I.

TABLE II

Type of onset articular damage

Groups	Damage: No total	No articular damage	Monoarticular Nr.	Monoarticular %	Oligoarticular Nr.	Oligoarticular %	Polyarticular Nr.	Polyarticular %	NPJ*	NSJ*
I	115	15	23	20%	60	52.17%	17	14.78%	11±5	8 ±3
II	65	0	2	3.07%	50	76.92%	13	20%	6 ± 3	4 ±3

**NPJ=number of painful joints*

**NSJ=number of swollen joints*

Rheumatoid arthritis is characterized by symmetrical polyarticular damage. Group I (seropositive patients) showed a higher number of affected joints and a more severely compromised quality of life: the average number of painful joints – 11 in group I *vs.* 6 in group II (t-Student=8.38; GL=178; p<0.001), mean number of swollen joints – 8 in group I *vs.* 4 in group II(t-Student=8.59; GL=178; p<0.001)(tab. II, fig. 3).

Fracture risk assessment plays an important role in the treatment of OP. FRAX, a recently developed algorithm of fracture risk assessment does not change the principle of defining OP as a decrease in T-score below -2.5 SD measured by DXA (tab.III, IV).

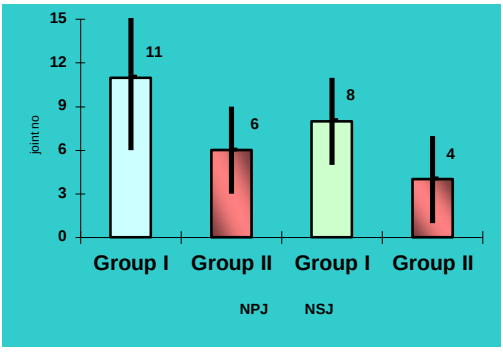

Fig. 3. Average number of affected joints in each study group

TABLE III

Fracture risk assessment

Gr.	Patient no.	Sex female %	Weight (60-75kg) %	Height (155-165cm) %	Fracture occurrence %	Parents with femoral neck fracture	Smoker %	GCS %	Secondary OP %	Alcohol use >3U/day %	**DXA 3-3,5 %**
I	115	100	73.9	69.5	23.47	11.20	4.35	92.17	15	5.74	34.78
II	65	95.65	68.7	83.7	9.23	6.4	2.45	80	3	1.3	16.92

TABLE IV
Fracture risk assessment

Groups	Risk	PATIENTS			
		WITH AT LEAST ONE FRACTURE		WITH NO FRACTURE	
		DXA-2.5	DXA-3.5	DXA-2.5	DXA-3.5
I		Risk 7.3	Risk 7.8	Risk 1.4	Risk 2.8
II		Risk 5.6	Risc 6	Risk 1.1	Risk 2.1

Using FRAX index, patients in group I with a T score of -2.5 measured by DXA had a 7.3% risk of fracture, and for a T score of -3.5 the risk was 7.8%. Patients in group II with a T-score of 2.5 had a risk of fracture of 5.6%, and for a T score of -3.5 the risk was 6%.

Severity criteria were comparatively assessed in the two study groups: NPJ > 6, significantly more common in group I patients (87%) compared to group II (χ^2=42.29; GL=1; p<0.001). NSJ > 6, significantly more common in group I patients (63%) as compared with group II (18%) (χ^2=40.17; GL=1; p<0.001). ESR > 28 mm/h, significantly more common in group I patients (58%) compared to group II (25%) (χ^2=21.09; GL=1; p<0.001). CRP > 20 mg/l, significantly more common in group I patients (82%) as compared with group II (28%) (χ^2=56.75; GL=1; p<0.001). ESR: group II: median = 25 +1 / 2 = 13; group I: median = 29 +30 / 2 = 29.5, CRP: group II: median = 14 + 15/2 = 14.5; group I median = 41 + 42/2 = 41.5; NPJ: group II: median = 21 +22 / 2 = 21.5, group I: median = 87 +1 / 2 = 44; NSJ: group II: median = 9 +10 / 2 = 9.5; Group I: median = 63 +1 / 2 = 32 (fig. 4).

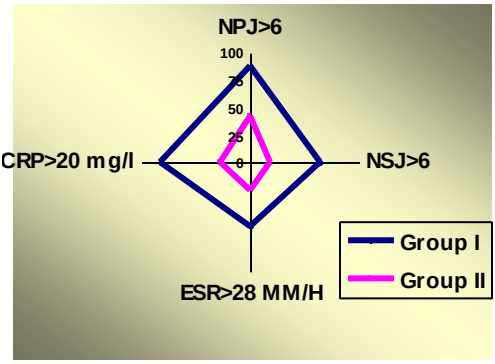

Fig. 4. Severity criteria in the two study groups

The *median* was used in assessing the severity criteria. The median is the middle value of a data set. It is the measure of center because to its left and to its right 50% of all data are found (fig. 4).

The biological factors of inflammation were most influenced in the seropositive form of disease, proving that this form is more severe.

Age distribution analysis showed that OP is common in the fifth decade of life as it is influenced by the presence of menopause (χ^2=23.60; GL=5; p=0.0003)(fig. 5, 6).

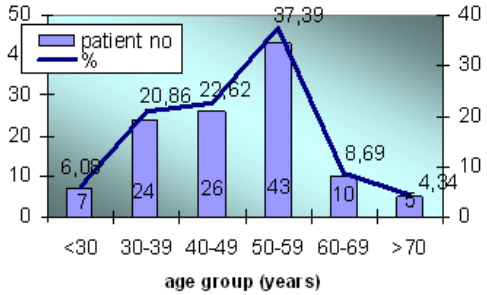

Fig. 5. Age distribution of osteoporosis patients in group I

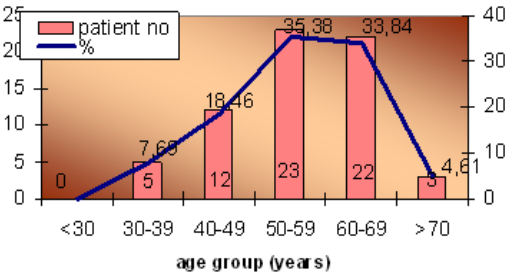

Fig. 6. Age distribution of osteoporosis patients in group II

Menopause is an important risk factor for OP due to hormonal and metabolic changes occurring after the menopause (2, 5, 6). Menopause was present in 89.56% of group I and 89.23% of group II patients, with a statistically insignificant frequency distribution (χ^2=0.56; GL=1; p=0.453). ESR and CRP correlated with disease activity, assessment of therapeutic outcome and prognosis. ESR reflects disease activity of the past few weeks, while CRP reflects short-term changes in disease activity. Case distribution in relation to ESR level showed no statistically significant differences between the study groups (χ^2=4.47; GL=1; p=0.346), but CRP was more common in group I patients (63.5%) as compared with group II (24.6%) (χ^2=23.56; GL=1; p<0.001).

Integument rheumatoid nodules were present in group I (p = 0.0003), but the distribution of cases with pulmonary fibrosis or vasculitis did not differ significantly between the two study groups.

TABLE V

Systemic effects in the study groups

GROUPS	PATIENT NO.	INTEGUMENT RHEUMATOID NODULES		PULMONARY FIBROSIS		VASCULITIS	
		No. %		No. %		No. %	
I	115	23 20	χ^2=13.16 GL=1 p=0.0003	25 21.73	χ^2=2.71 GL=1 p=0.0997	7 6.08	χ^2=0.29 GL=1 p=0.593
II	65	0 0		7 10.76		2 3.07	

Rheumatoid factor measured by Latex and Waaler Rose (4) is one of the diagnostic criteria and it differentiates seropositive from seronegative forms having a high negative prognostic value, correlated with the highly erosive characteristic of the disease, marked functional impairment, articular index (radiological), and presence of systemic manifestations (fever, Raynaud's syndrome) (4). Rheumatoid nodules were found only in patients with seropositive forms of disease, who showed an increased occurrence of systemic effects. Radiological changes showed significantly more erosions in group I (p = 0.003). Distribution of cases

with geodes, impingement of the joint or juxtaarticular osteoporosis showed no significant differences between the two study groups (tab. V, VI).

TABLE VI

Radiological changes

GROUPS	GEODES		EROSIONS		IMPINGEMENT OF THE JOINT		JUXTAARTICULAR OSTEOPOROSIS	
I	63	χ^2=0.01 GL=1 p=0.904	98	χ^2=9.04 GL=1 p=0.003	75	χ^2=0.01 GL=1 p=0.935	96	χ^2=0.70 GL=1 p=0.404
II	35		47		42		58	

Group I, with marked impairment in a great number of joints, had more advanced OP. The radiologic examination showed that the seropositive form of RA had a severe evolution(χ^2=8.21; GL=2; p=0.017). *Corticosteroid* (CS) therapy had a negative impact on bone metabolism, increasing bone resorption and decreasing bone formation, resulting in reduced bone mass and increased fracture risk. It is thus an important risk factor for OP, especially in group I. 92.17% of patients in group I and 80% of patients in group II received this therapy (p = 0.031).

Reduced bone formation is caused by the direct effects of CS on osteoblastic cell line and by indirect mechanisms, such as inhibition of gonadotropin release and of sex steroid formation. CS causes a degradation of type I collagen (the major constituent of bone matrix), which explains the inhibitory action of CS on bone matrix and bone mass.

A direct relationship between CS treatment, duration and dose of PDN was shown. Patients who received CS treatment more than a year had osteoporosis. The PDN dose of 5-7.5 mg / day showed the lowest risk of OP (tab. VII).

TABLE VII

Patients receiving corticoterapy

GROUPS	PATIENT NO.	PATIENTS RECEIVING CS TREATMENT	STATISTICAL DIFFERENCE
		Nr. %	
I	115	106 92.17	χ^2=4.66 GL=1 p=0.031
II	65	52 80.00	

Anti-osteoporotic therapy considered the severity of bone loss and fracture risk, the individual contraindications, and the availability of a specific product used by the study group (3.7). All OP drug therapies influence bone metabolism (*turnover*). Anti-osteoporotic therapy showed a good outcome in our study groups and was administered at approximately the same doses in both study groups (p = 0.729) (tab. VIII).

TABLE VIII

Patients receiving anti-osteoporotic therapy

GROUPS	TOTAL NO.	PATIENTS RECEIVING ANTI-OSTEOPOROTIC THERAPY	STATISTICAL DIFFERENCE
		Nr. %	
I	115	61 53.04	χ^2=0.12 GL=1 p=0.729
II	65	37 56.92	

Biological therapy - clinical and biological improvement occurred early in all patients treated with MTX at a dose of 7.5 mg/week in association with biological therapy with infliximab (Remicade) 3 mg/kg/infusion (mean dose provided by international algorithms for the use of this product).This way, a decrease in disease activity score level was achieved, which correlated with improvement in the other quantifiable parameters. Biological therapy was used in about the same proportions in both study groups (p=0.518); it has remarkable results in rheumatoid arthritis therapy, as it can lead to RA remission (tab. IX).

TABLE IX

Patients receiving biological therapy

GROUPS	PATIENT NO.	PATIENTS RECEIVING BIOLOGICAL THERAPY	STATISTICAL DIFFERENCE
		Nr. %	
I	115	69 60	χ^2=0,42 GL=1 p=0.518
II	65	35 53.84	

Kinesiotherapy was a treatment method used in both study groups (p = 0.257). The physiotherapy program included the same exercises for patients in the two groups. The physical therapy program was designed to meet the general principles of kinesiology: specificity, progressiveness and reversibility (tab. X).

TABLE X

Patients receiving kinesiotherapy

GROUPS	PATIENT NO.	PATIENTS RECEIVING KINESIOTHERAPY	STATISTICAL DIFFERENCE
		Nr. %	
I	115	41 35.65	χ^2=1.29 GL=1 p=0.257
II	65	23 35.38	

Balneo-physical therapy must be given with great caution in patients with rheumatoid arthritis and it may relieve pain, inflammation, strengthen muscles and prevent osteoporosis.

Monitoring the development of disease

Using the ROC curve to show the comparative effectiveness of treatment in the two study groups revealed that the anti-osteoporotic treatment was effective, with

an accuracy of 63.9%, followed by the biological treatment, with an accuracy of 63.2% (tab. XI, fig. 7).

EULAR response - the number of patients with a good or moderate response was significantly higher in group I as compared with group II (χ^2=10.19; GL=2; p=0.006) (tab. XII).

TABLE XI

Comparative analysis of the results of therapy methods

Therapy	PPV (%)	NPV (%)	Sensitivity (%)	Specificity (%)	Accuracy (%)	p

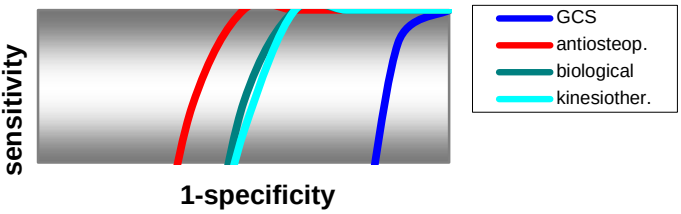

Fig. 7. TheROC curve for the effectiveness of treatment

TABLE XII

Monitoring the development of disease

GROUPS	PATIENT NO.	DEGREE OF THERAPEUTIC RESPONSE		
		PATIENTS WITH A GOOD RESPONSE (>1.2)	PATIENTS WITH A MODERATE RESPONSE (0.6-1.2)	PATIENTS WITH NO RESPONSE (≤0.6)
		Nr. %	Nr. %	Nr. %
I	115	28 24.34	39 33.91	48 41.73
II	65	21 32.30	32 49.23	12 18.46

Age distribution of the study groups shows an increasing incidence of the disease from the fourth decade of life onwards. The seropositive form of the disease has an earlier onset than the seronegative one, and this is reflected in a higher number of affected joints, the Steinbroker functional classrevealing a more severely compromised quality of life in group I patients.

The biological factors of inflammation - ESR and CRP - correlate with the evaluation of disease activity (DAS28), with the therapeutic response and prognosis evaluation. These parameters of inflammation were high in group I, showing that the seropositive form of the disease progresses faster and more

severely. C-reactive protein value was independent of the disease duration. Pain assessment (pain is the main complaint in RA patients) was made using a visual analogue scale (VAS) and showed an increased frequency of pain in the patients with a longer disease suration. Therefore, there is a direct correlation between pain and disease duration. A direct correlation between HAQ scores and duration of disease was also noted, and HAQ was higher in seropositive patients.

The age distribution of osteoporosis patients showed a peak in the fifth decade of life and menopause contributed to this peak, as menopause was present in 84.61% of the patients in group I and 89.23% in group II. DXA showed important pathological features in the seropositive group I, indicating a more severe form of disease. The radiological examination revealed a risk of fracture: 23.47% of group I patients had at least one fracture and only 9.23% of group II patients. Correlating with DXA assessment, a T score of <-3.5 in 13.04% of group I and 9.23 of group II patients, a high risk of fracture was observed, it being higher in the seropositive group I.

CONCLUSIONS

Osteoporosis in RA patients has a severe course, inducing disability and affecting furthermore the their quality of life. However, the quality of life may be improved by early treatment. Osteoporosis and "rheumatoid" osteopenia appear to be independent of individual indicators of disease evolution, but they are directly related to the low values of composite indices. The low functional capacity favors bone loss in RA patients.

Research has provided evidence that the pathogenesis of osteoporosis involves a complex interaction of genetic and environmental factors, affecting bone growth, peak bone mass, calcium homeostasis and bone loss and it is influenced by age, physical inactivity, hormonal deficiency and vitamin D metabolism.

MANGANESE INTERACTIONS WITH DOPAMINERGIC SYSTEM

Diana Ciubotariu, M. Nechifor
University of Medicine and Pharmacy „Grigore T. Popa" - Iasi
Faculty of Medicine
Discipline of Pharmacology

MANGANESE INTERACTIONS WITH DOPAMINERGIC SYSTEM (Abstract): Manganese is a trace element with important involvement in the central nervous system functioning. The effects of manganese excess on central dopaminergic system in case of both basal nuclei and reward system are linked to important pathologic states such as Parkinsonism and cognitive impairment. Our data show that Mn^{2+} reduces the intensity of experimental morphine addiction in rats (manganese chloride unequally decreases several symptoms of opioid withdrawal syndrome – signs such as compulsive mastication, grooming and teeth chattering being particularly affected). Manganese chloride, administered during conditioning acquisition phase in rats, significantly reduces the intensity of morphine conditioned place preference. We believe that manganese interaction with dopaminergic circuits in the brain reward system represents one of the most important aspects of the action of bivalent cations at central nervous system level. **Keywords**: MANGANESE, DOPAMINE, BRAIN REWARD SYSTEM, MORPHINE-DEPENDENCE, PLACE PREFERENCE.

Bivalent cations, either macro- or trace elements, are present in different concentrations in the central nervous system (CNS). Most of them play complex roles in the functioning of CNS, neurons, glial tissue or blood vessels. There is increasing evidence referring to the complex regulatory action determined by the bivalent cations on CNS. This regulatory action has three different essential items: modulation of enzymatic activity (most enzymes contain a bivalent cation as co-factor or allosteric modulator); modulation of synthesis and activity of different neurotransmitters (presynaptic release, re-uptake etc); modulation of neurotransmitter action at receptor site.

Manganese is an essential trace element with important catalytic and structural roles. As in the case of other bivalent cations deficiency and excess, in case of Mn^{2+} misbalances dysfunctions in the activity of numerous organs and systems (including CNS) were identified. Mn^{2+} excess is more frequently encountered and has more severe consequences than Mn^{2+} deficiency, determining mainly neurological and psychiatric disturbances.

Human body contains approximately 10 – 20 mg of manganese. It is considered that serum Mn^{2+} level should be lower than 1.4 μg/100 mL. The most important Mn^{2+}-dependent enzymes include: glycosyltransferase, phosphoglucomutase, different kinases, hydrolases (including phosphatases), decarboxylases, pyruvate carboxylase, peptidases (arginase), cholinesterase, and mitochondrial superoxide dismutase (1).

The highest CNS Mn^{2+} concentrations are in nucleus pallidus, as well as in other regions with predominant dopaminergic neurotransmission. Also, brain dopaminergic sites are concentrating most of the Mn^{2+} excess, both in case of chronic exposure or hepatoportal encephalopathy (2). There is no correspondence relationship between serum and brain Mn^{2+} concentrations: while increased Mn^{2+} serum concentration may revert to normal after exposure is stopped, brain Mn^{2+} levels continue to be increased. Little is known about Mn^{2+} passage through brain-blood barrier. Aschner et al., 1999 (3), showed that manganese, as a citric acid salt, is better captured by the cerebral tissue compared to free Mn^{2+}cations. In the lateral choroid plexus, there are mechanisms protecting against Mn^{2+} ions passage into the cerebral-spinal fluid in case of high blood Mn^{2+} concentrations (4). Sloot et al., 2004 (5), have shown that Mn^{2+} is captured by dopaminergic and GABAergic neurons in substantianigra, and that there are mechanisms for the axonal transport of the cation. Also, chronic Mn^{2+} exposure determines its accumulation into astrocytes (6). The most characteristic aspect regarding Mn^{2+} excess in the CNS is represented by the occurrence of Parkinson-like disease syndrome. Chronic Mn^{2+} administration and intoxication are used as experimental models of induced Parkinson disease in animals (7). Extrapyramidal phenomena can be reproduced, for example, by the administration of 5mg/kg/day Mn^{2+}, for 2 to 8 weeks in rats.

I. Mechanisms of manganese-induced central nervous system toxicity

CNS is the main target of Mn^{2+} toxicity. Even though data on the mechanisms by which Mn^{2+} determines its toxic effect on the CNS are not very clear, the hypothesis of increased oxidative stress, followed by a reduction in mitochondrial anti-oxidant protectionsystem, is ever more considered (8):

1. Fitsanakis et al., 2006 (9), have demonstrated that intra-cellular Mn^{2+} is sequestrated by the calcium-importer system in the mitochondria, and that neuronal mitochondria are particularly sensitive to Mn^{2+} toxic activity (Mn^{2+} inhibits oxidative phosphorylation);

2. A possible explanation for the long term Mn^{2+} neurotoxic effect related to chronic exposure may be the following: excess brain Mn^{2+}cation levels are oxidized to superior valence forms, and therefore catecholamine, and particularly dopamine oxidation is enhanced (10; 11);

3. Manganese also determines an increase in H_2O_2 neuronal generation, probably as a consequence of reduced catalase activity (12);

4. Also, the increased oxidative stress hypothesis to explain Mn^{2+}-induced neurotoxicity was suggested by Prabhakaran et al., 2008 (13), who incriminated NF-κB induction and the activation of nitric oxide synthesis through NOS (nitric oxide synthase) as a probable mechanism for Mn^{2+} CNS toxic effects;

5. Manganese induces caspase activation and DNA fragmentation;

6. Another possible hypothesis for Mn^{2+} brain cytotoxic effects is linked to metabolism impairment. Glucidic metabolism is particularly affected. Especially in astrocytes, glycolytic activity inhibition may result in the accumulation of toxic glutamine.

Central dopaminergic systems are particularly affected by Mn^{2+} excess. A significant and long-lasting dopaminergic depletion (tens of years after exposure is stopped) is recognized as a consequence of

Mn^{2+} exposure. Mn^{2+} excess is considered dopaminergic neurotoxin, and Hamai et al., 2001 (14), show that Mn^{2+} is highly effective in blocking dopaminergic neurotransmission. Chronic exposure to Mn^{2+} is associated with lesions in the basal ganglia neurons. Intrathecal Mn^{2+} administration in rats is followed by dopaminergic depletion, especially in the caudate-putamen regions. Manganese phosphate ($MnPO_4$) is more potent than manganese sulphate ($MnSO_4$) and manganese chloride ($MnCl_2$) in producing dopaminergic depletion (15). The selectivity of Mn^{2+} toxicity for the regions rich in dopamine does not have a clearly elucidated cause, but there are some partial explanations. For example, Anderson et al., 2007 (16), proved that Mn^{2+} accumulation in dopaminergic neurons in globuspallidus is at least partially dependent on dopamine transporter (DAT), as by inhibiting DAT with GBR12909 substance (1 mg/kg, 3 times a week, for 4 weeks) Mn^{2+} accumulation is stopped and Mn^{2+} levels show a significant decrease in that region. A study by Hirata, 2008 (17), contradicts the idea that toxicity determined by Mn^{2+} in the PC12 cell line is DAT-dependent, as Mn^{2+}-induced DNA fragmentation is present in both PC12 cells over-expressing DAT and in PC12 control cells (although the latter are affected at slightly higher doses); however DAT inhibitors (such as mazindol, nomifensine, or GBR12909), inhibit MPP+-induced DNA fragmentation.

As dopaminergic systems are particularly sensitive to the influence of Mn^{2+} ions, Mn^{2+} causing, as shown above, dopaminergic depletion, several studies were focused on different aspects of the interactions between Mn^{2+} ions and dopaminergic neurotransmission, including dopamine synthesis, release, action at specific receptor site, re-uptake, and metabolism. Different Mn^{2+}-induced effects on the above-mentioned aspects of dopaminergic neurotransmission were evidenced. Some of them are quite contradictory and some of the studies do not support the idea that Mn^{2+} impairs dopamine functions at any of its levels.

a. ***Dopamine synthesis***. Bonilla et al., 1980 (18) reported that following Mn^{2+} chronic treatment in rats the enzymatic activity of L-tyrosine hydroxylase (an enzyme involved in catecholamine synthesis) is increased. The augmented enzymatic activity persisted in neostriatum, midbrain and hypothalamus on the third month and remained elevated only in neostriatum on the sixth month. After eight months a significant decrease in the activity of the enzyme was found in neostriatum with no changes in the remaining studied regions. Also, in male albino rats exposed to $MnCl_2 \cdot 4H_2O$ (1 mg/ml) through drinking water there is an initial increase in the stream dopamine level, followed by a period when concentration is almost normal (from 120 to 240 days) (19). Thereafter, the contents of dopamine declined significantly at 300 and 360 days of treatment. Mn^{2+}, 125-520 μM in cell culture increases intracellular concentrations of L-Dopa (catecholamine precursor) (20). These findings are in agreement with the fact that human Mn^{2+} intoxication starts with a psychiatric phase bearing similarities to schizophrenia in which the primary disturbance has been suggested to be an over-activity of dopamine neurons. A totally different situation is in newborns compared to adults. Neonatal rats, intubated daily with distilled water, 25 or 50 μg $MnCl_2$/g/day for 14 or 21 days (starting from the day of birth) did not show significant changes in norepineph-

rine, dopamine, serotonin and their metabolites in the striatum, hypothalamus, and nucleus accumbens, though Mn^{2+} brain levels were significantly higher than in controls. The developing CNS may be able to counteract neurochemical changes caused by Mn^{2+} exposure.

b. ***Dopamine release***. Semama et al., 1995 (21) have demonstrated partial Mn^{2+} blocking of calcium channels in renal blood vessels. If this action also takes place in the cerebral tissue, this may explain a possible Mn^{2+}-induced alteration of glutamate ability to stimulate dopamine release. On the other hand, chronic Mn^{2+} exposure results in a marked decrease of in vivo dopamine release, in the absence of a change in markers of dopamine terminal integrity or dopamine receptors in the striatum (22).

c. ***Dopamine – specific receptors binding***. Butterworth et al., 1995 (23) showed that Mn^{2+} potentiates dopamine binding to specific receptors. On the other hand, Mn^{2+} seems to determine a reduction in dopamine receptors antagonists binding to their specific sites. In monkeys with Mn^{2+} intoxication, the specific D1 receptors antagonist SCH 23.390 expresses a lower binding to specific receptors compared to controls (24). Chronic manganism is associated with markedly decreased D2 receptor density, especially in the striatum (25).

d. ***Dopamine re-uptake***. Chen et al., 2006 (26) proved in a study on primates (baboons) that acute manganese sulphate (MnSO4) administration determines a decrease in dopamine binding to DAT (dopamine transporter), but a significant increase in DAT level (probably compensatory to the decrease in dopamine binding capacity), while dopamine re-uptake is inhibited.

Our data show a reduction in the intensity of both morphine physical dependence and morphine-induced conditioned place preference by Mn^{2+}. We have found a significant reduction in morphine dependence intensity by the administration of $MnCl_2$ (0.1 mEq/kg/day, 10 days) (27, 28). Compulsive mastication, teeth chattering and grooming are particularly reduced by manganese administration ($p<0.01$ vs. morphine-only treated group), while locomotor activity, weight loss, aggressive postures are moderately reduced ($p<0.05$). Global withdrawal score GellertHolzmann is also reduced ($p<0.01$). The influence on withdrawal symptoms is therefore unequal and dose-dependent ($MnCl_2$ administration, 0.05 mEq/kg/day, has no influence on morphine global withdrawal score, reducing only teeth chattering and grooming, $0.01<p<0.05$). As $MnCl_2$ was administered during morphine dependence induction phase and not during withdrawal, we consider this not to be a direct effect of manganese on morphine withdrawal, but on the intensity of morphine-dependence. The intensity of morphine induced conditioned place preference in rats is reduced by $MnCl_2$, (0.1mmol/administration, administered 2 hours before morphine, in the conditioning acquisition phase; 0.01mmol/kg/day, 10 days before preconditioning) (29). We believe that decreases in both morphine dependence intensity and morphine behavioral effects represent important proofs of the consequences of Mn^{2+} excess and support that their mechanism is related to dopamine neurotransmission impairment. Glutamatergic system is particularly sensitive to manganese actions, glutamate being one of the neurotransmitters mainly involved in the addictive processes. A subacute manganese exposure (7 to 21 days) in mice is sufficient to alter presynaptic do-

pamine release in the striatum (30).

II. Clinical consequences of the interactions between manganese and dopaminergic neurotransmission and of manganese excess

Chronic Mn^{2+} intoxication is characterized by weakness, headache, muscle cramps, loss of appetite, apathy, insomnia, diminished libido, which are associated with psychotic reactions known as *"locura manganica".* This "manganese madness" is characterized by aggressive manifestations and emotional lability. Characteristic clinical signs often include extrapyramidal symptoms such as bradykinezia, tardive dyskinesia (myoclonic movements), akathisia, dystonia (31). Other symptoms are less common and include behavioral impairment. As a consequence of manganese toxicity, symptoms such as confusion, monotone voice, un-expressive face, spastic movements and disturbed gait, hallucinations, renal failure may also appear. Mn^{2+} excess also impairs cognitive capacity (learning and memorization skills). There is a very clear relationship between manganese excess and dopamine central circuits which explain the behavioral disorders and cognition impairment associated with Mn^{2+}; taking this into consideration, new perspectives are opened for human clinical studies.

SIDE EFFECTS OF ANTIVIRAL THERAPY IN HEPATITIS C VIRUS INFECTION – SARCOIDOSIS (CASE REPORT) (Abstract): Standard therapy in chronic hepatitis C virus infection is still a combination of peginterferon alfa2a/2b and ribavirin for 48 weeks. As of side effects, there are organic side effects, such as hematologic disorders, and functional side effects, reflected in the quality of life of hepatitis C patients. Up to 30% of the patients develop specific side effects such as headache, fever, fatigue. Sarcoidosis, known as a granulomatous disease of uncertain cause, is an uncommon finding in this category of patients. This cause-effect relation is accounted for by the convergent action of peginterferon and ribavirin of stimulating type 1 T helper cells and reducing type 2 helper T cells activation. We present the case of male patient known with chronic hepatitis C who developed pulmonary sarcoidosis following antiviral therapy**.** The first manifestation of the disease was unexplained fever accompanied by pulmonary tract disease. The diagnosis was established by immunophenotyping in bronchial aspirate **Keywords**: HEPATITIS C, INTERFERON ALPHA, SARCOIDOSIS.

Combination therapy using peginterferon alpha2 a/2b and ribavirin for 48 weeks is still the gold standard of treatment for chronic hepatitis C. Nearly 30% of patients develop nonspecific side effects (headache, fever, fatigue) during this treatment. Sarcoidosis associated with this therapy is rare, being described in less than 1% of hepatitis C patients. The association between sarcoidosis and antiviral therapy is explained by the immunomodulatory action of both substances expressed in the stimulation of type 1 T helper (Th1) cells activity and decrease in type 2 T helper lymphocytes (Th2) activity. We present a case of sarcoidosis diagnosed in a patient with chronic hepatitis C treated with peginterferon alpha-2a and ribavirin.

CASE REPORT

MD, 43-year-old male, was diagnosed in 2009 with chronic HCV infection (HCV RNA - 907,000 IU/ml; pathology findings: chronic hepatitis of moderate activity Ishak ANI score = 7, fibrosis = 3, metavir A_2F_2). Based on liver function testing, antiviral therapy with peginterferon alpha-2a (180 mcg/week) and ribavirin (1000 mg/day) was initiated. As the 4-month assessment revealed that viral load became undetecta-

ble, the patient continued the initially recommended therapy. Also, during this period no notable side effects were reported. Starting with the fifth month of antiviral treatment the patient complained of fever, chills, sweating, fatigue, chest pain, and headache. Physical examination revealed fever 38°C, submandibular adenopathy, and sonorous and subcrepitant rales in the right lung area. Laboratory findings: severe thrombocytopenia without radiological pulmonary changes (tab. I).

TABLE I
Laboratory findings during febrile syndrome

Z 1	Z 7	Z 14
Hb – 12,4 g%	Hb – 11,4 g%	Hb – 12.2 g%
GA – 5.080/mm^3	GA – 2540/mm^3	GA – 2800/mm^3
Tr – 48.000/mm^3	Tr – 101.000/mm^3	Tr – 100.000/mm^3

Discontinuation of antiviral therapy for 7 days and administration of single-drug antibacterial therapy for 2 days (ampicillin), and then, because of febrile syndrome persistence, administration of dual antibacterial therapy (Ampicillin - Ciprofloxacin) were decided. Radiological reassessment after 7 days of antibacterial therapy detected a focus of right infrahilar condensation. Clinically, the respiratory manifestations gradually faded within 14 days, and biologically an improvement of thrombocytopenia was found. Radiological examination at 21 days revealed a decrease in size of the initial inflammatory focus. Clinical and biological monitoring during the remaining seven months of antiviral therapy showed fluctuations in platelet and leukocyte count, reason why no temporary reductions in antiviral drug dosage were necessary. Clinically, the patient continued to complain of fatigue, intermittent fever, and dry cough. As these manifestations have not outlined any ongoing clinical syndrome, they were classified as clinical adverse reactions of antiviral therapy and treated symptomatically.

After 48 weeks of antiviral medication, the patient complained again of respiratory manifestations: progressive dyspnea, and cough with purulent expectoration. Radiological examination revealed bilateral hilar lymphadenopathy (fig. 1). Additional tests detected significant pulmonary and cardiac changes (tab. II).

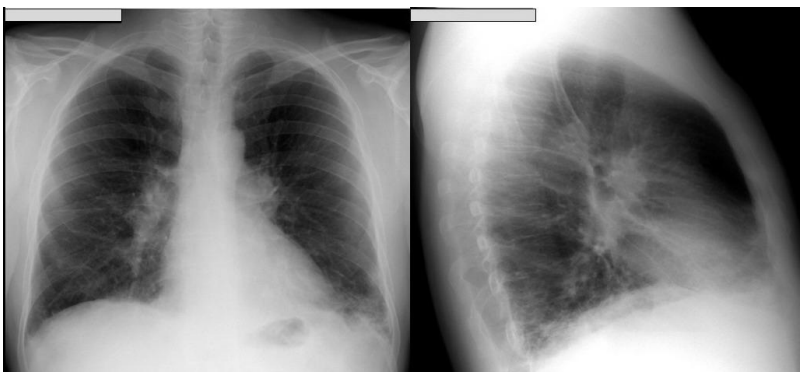

Fig. 1. Bilateral hilar lymphadeopathy

TABLE II

Additional examination 50 weeks after the initiation of antiviral therapy

- IDR 2u PPD – negative
- Fibrobronchoscopy: friable mucosa, abundant secretion
- Bronchial aspirate – BAAR negative
- Anatomopathological examination of bronchial aspirate - inflammatory smear with metaplasia and moderate dysplasia
- Bronchial aspirate immunophenotyping - 21% Ly, 20% - LT, TCD4/CD8 ratio = 3.3
- Pulmonary function tests: FEV1 - 77.7%, FVC - 77.4%, PEF - 90.1%, MEF50 - 64.1%. Conclusion: mild restrictive dysfunction
- ECG - sinus rhythm, supraventricular extrasystoles with aberrant conduction
- Chest CT (fig. 2):
  - mediastinal lymph nodes: enlarged, confluent, bilateral and relatively symmetric, noncalcifed, without necrosis, uncompressed
  - parenchymal changes: round, small, perilymphatic nodules, nodular or irregular areas of increased „ground glass" attenuation, and peripheral, subpleural peribronhovascular condensations
  - retroperitoneal lymph nodes, interaorticocaval ~ 2cm, celiomesenteric < 1cm

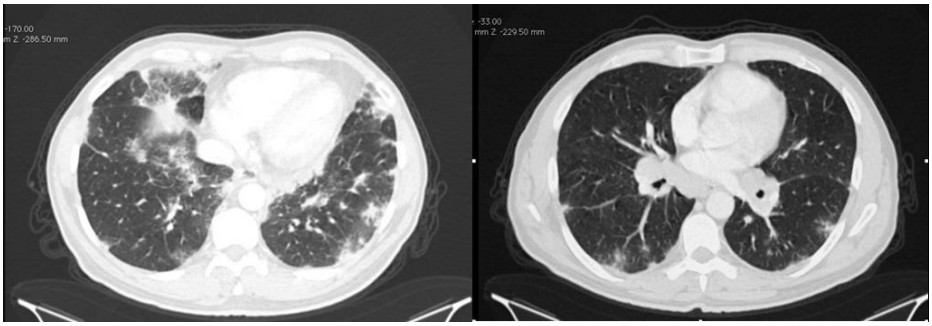

Fig. 2. Mediastinal lymphadenopathy

As the patient did not present peripheral adenopathy and the risk of a mediastinal biopsy was higher that its benefit (immunosuppressed background), this test (pathology) required for differential diagnosis (tuberculosis, lymphoma, sarcoidosis) was not performed. Phenotypic analysis of bronchoalveolar lavage sample (Tab. II) showed criteria suggestive of sarcoidosis. In the absence of other consistent evidence for a diagnosis of lymphoma or tuberculosis, we interpreted these findings as stage II sarcoidosis. Prednisone therapy was instituted; fever disappeared after a week, the patient being monitored by an infectious disease specialist. Viremia after 18 months of therapy remained undetectable.

DISCUSSION

The first case of sarcoidosis associated with interferon therapy was published in 1978. Since then, similar cases have been reported in the literature, but not being a widespread phenomenon it did not lead to

the cessation of the above mentioned therapy (3)

Chronic hepatitis C infection currently affects over 170 million people worldwide. Current standard therapy of this disease is the association of two antiviral drugs (peginterferon alpha2a/2b - ribavirin) with immunomodulatory role, amplifying the immune system response on infected cells. (2). In 40-50% of cases, subjective side effects (fatigue, myalgia, headache, depression) and others representing well-defined organ dysfunctions (e.g. autoimmune thyroiditis) are reported.

Sarcoidosis diagnosed in patients on antiviral treatment for hepatitis C is recognized as a side effect of interferon therapy. Interferon-induced sarcoidosis is known to be a chronic multisystem inflammatory disease of unknown cause manifest by the appearance of non-caseous granulomas in various organs/systems: lung (90%), lymphatic system (33%), liver (50/80%), eyeball (11-83%), and skin (25%).(1) As to its pathogenesis, it requires the intervention of one or more factors (infectious, tumor antigens/autoantigens) that prime immune mechanisms through which a prolonged stimulation of T lymphocytes with the appearance of an exaggerated T-helper cell response is produced: predominance of Th1 cells over Th2 cells. Interferon-alpha stimulates Th1 cell differentiation and decrease in Th2 lymphocytes activity leading to the formation of granulomas (6, 8). Compared to its predecessor, peginterferon-alpha has a higher influence on Th1 response, and therefore an increased risk for sarcoidosis. (4, 5, 9) Ribavirin, guanosine analogue, also stimulates Th1 lymphocytes and decreases Th2 lymphocyte activity. Thus, this association accounts for the increased predisposition to sarcoidosis of hepatitis C patients on antiviral therapy. In this category of patients, sarcoidosis can occur during treatment or after its discontinuation (7).

We presented a case of pulmonary sarcoidosis induced by peginterferon-alpha2a - ribavirin antiviral therapy in a 43-year-old patient. In this patient the onset of prolonged febrile syndrome associated with respiratory symptoms occurred after the first four months of therapy. In the absence of clear evidence (absence of superficial or deep lymph nodes), the clinical picture was initially interpreted as a right lower lobe pneumonia favored by drug induced leukopenia. Fever, fatigue, and cough are frequent adverse reactions in patients on long-term antiviral therapy. Our interpretation of patient's symptoms was revised only when after antiviral treatment discontinuation at 48 weeks radiological examination showed a bilateral hilar lymphadenopathy. Pulmonary examinations completed this information puzzle leading to a correct interpretation of the picture. Bronchoalveolar fluid immunophenotyping is the key diagnostic test on which the disease was diagnosed in the absence of other criteria.

CONCLUSIONS

Antiviral therapy with peginterferon alfa2a/2b and ribavirine in patients with hepatitis C has many functional and organic side effects. Before therapy, these reactions, which can be temporary, have to be divulged while obtaining consent. During the long-term antiviral therapy the physician has to pay attention to all side effects that can appear and take measure for preventing or diminishing their actions. Sarcoidosis is an uncommon occurrence, and in our case we misinterpreted the first disease manifestations: fever of unknown origin and pneumonia. Following the detection of mediastinal adenopathy, the addi-

tional investigations made us realize that all manifestations could be interpreted as pulmonary sarcoidosis. Therapy with prednisone was initiated and fever disappeared within a week. So it is important to keep in mind that respiratory disorders occurring in hepatitis C patients on antiviral therapy can be early signs of sarcoidosis.

NEWS

EXPOSURE TO CIGARETTE SMOKE AND THE PATHOGENESIS OF RESPIRATORY INFECTION

Staphylococcus aureus, conditioning pathogenic bacteria, can colonize the upper respiratory tract and can cause severe infections under favorable conditions such as exposure to cigarette smoke (CS). CS has immunosuppressive and irritant effects on human cells. A recent study released by Kulkarni R and colleagues show that CS also affect the microorganisms by normal microbiota and potentiate their virulence. CS increased *S. aureus* ability to form biofilm and to adhere to the host cell. Oxygen free radicals present in CS inhibit Accessory Gene Regulator (agr) system responsible for dispersing bacterial biofilms. Also these compounds determine transcriptional induction of bacterial oxidoreductases. By inducing transcription of fnbA (encoding fibronectin binding protein A), increases the ability of *S. aureus* to bind fibronectin and thus CS can favor bacterial adherence to the host cell. This study concluded that the bioactive effects of CS may extend to the resident microbiota with implications for the pathogenesis of infection (Kulkarni R, Antala S, Wang A et al. Cigarette smoke increases Staphylococcus aureus biofilm formation via oxidative stress. *Infect Immun*, 2012; 80 (11): 3804-11).

QUALITY OF LIFE IN PATIENTS WITH ULCERATIVE COLITIS (Abstract) : Patients with inflammatory bowel disease (IBD) have to live with the perspective of a potential disability, which may lead in time to impaired quality of life (QoL). In order to fully understand the impact of IBD on patients and their careers we need to quantify the QoL**. Aim**: To evaluate HRQol in ulcerative colitis patients as opposed to the general population and to identify the significant changes of HRQoL in accordance with the specific progression of UC. **Methods**: The prospective study (January 2010 - December 2012), included 105 patients with ulcerative colitis (UC). Disease activity was quantified by means of the Truelove and Witts score (mild, moderate and severe). All patients were administered a self-completed IBD questionnaire (IBDQ). Lower scores were related to a worse QoL. Statistical analysis was performed and differences were considered significant when $p \leq 0.05$. **Results**: Ninety-one percent (91%) were admitted with a flare, while they were asked to fill in the IBDQ. Proctitis was met in 2.94% of the cases, left-sided colitis in 71.1% and pancolitis in 26%. There were 32 patients with mild activity, 62 with moderate activity and only 3 with severe activity. The range score for QoL was 90-180. In proctitis: 80- 190, in left-side colitis: 120- 200, in pancolitis: 70- 160 ($p>0.05$). The patients with severe form had a lower score (50-140) than patients in remission (130-180) ($p<0.01$). **Conclusion**: Patients with UC have significantly influenced the QoL as compared to the general population. We found no significant differences regarding the extension of the lesions. The severity of the flare had a significant impact on the QoL. **Key words**: QUALITY OF LIFE, ULCERATIVE COLITIS, STATISTICAL ANALYSIS.

The "quality of life" (QoL) concept has been taken into consideration and studied ever since 1946, when World Health Organization defined health as "a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity" (1).

Quality of life represents a "holistic self-assessment of satisfaction, with reference to the individual", being a highly controversial multidimensional concept, which is difficult to define, although it seems quite easy to grasp its meaning (2, 3, 4).

The term "health-related quality of life" (HRQoL) was defined as being the functional effect of a disease and the treatment of the patient, as it is perceived by the patient. The patient's perception of his health

is vital for understanding the way in which he/she organizes his/her activity. HRQoL may be influenced by a number of factors such as: financial status, habitat, job, spirituality, social support, and, last but not least, the health of the individual.

Although they represent different concepts, functional status and HRQol are used together in clinical practice. Functional status reflects the ability to fulfill daily activities (physical, social, and emotional), while HRQoL takes into account the subjective, personal aspects of the impact, the health status on the quality of life of the individual (5).

Ulcerative colitis (UC) is a chronic disease with an unpredictable evolution, marked by episodes of both activity and remission. Patients with UC are affected not only by the physical effects of the disease, but also by the impact it can have on the QoL.

The instruments of assessing HRQoL are represented by general questionnaires, and disease-specific questionnaires. These questionnaires assess HQoL by calculating a score on account of the patient's perception on HRQoL. The HRQol score reflects the evaluation of the life lived in a specific state of health, having the patient himself as the primary source of information.

The aim of this study is to evaluate HRQol in ulcerative colitis patients as opposed to the general population and to identify the significant changes of HRQoL in accordance with the specific progression of UC.

MATERIAL AND METHODS

A prospective case-control analytic study has been conducted inside the Gastroenterology and Hepatology Center in Iaşi over a period of 50 months (January 2010 - February 2012). The study included 189 patients, assigned to 2 groups: Group A, containing 105 patients with UC, and control Group B, containing 84 patients without UC.

The UC diagnostic was supported by complete hematological and biochemical tests and colonoscopy and, also, histopathologically. The activity of the disease was quantified by means of the Truelove - Witts score.

Patients were evaluated based on questionnaire IBDQ-32. This is one of the most widely used HRQoL evaluation questionnaires. It contains 32 questions grouped into four areas: gastrointestinal symptoms (diarrheic stools, abdominal pains, rectal bleeding, tenesmus), systemic symptoms (fatigue, sleep disorder), emotional functions (depression, irritability, anger), and social functions (absenteeism, affected social status). The answers range from 1 (the worst) to 7 (the best). Total score ranges from 32 to 224. The lower the score, the more HRQoL is affected (5).

Patients with UC were asked to send the IBDQ-32 questionnaire to someone they know, without UC, of the same age and sex, in order to make up the control group.

In order to process and interpret the data, *MS Excel*, *EpiInfo*, and *SPSSS* computer software were used. The interpretation also contained a descriptive analysis and the following tests: χ-square, t-Student. The differences were considered significant when $p \leq 0.05$.

RESULTS

Structure of the studied group

The group of 105 patients diagnosed with UC consisted of 42 men (40%) and 63 women (60%). The average age was 42.67 (+/- 13.74), the ages of 22 and 63 being the extremes. Most of the patients were living in an urban area - 70 (66%), with only 35

(33%) of them living in a rural area. The non-smoking status was predominant, 60 patients being non-smokers (57.14%), while 45 patients were smokers (42.85). The disease duration had an average of 29.3 months (+/- 30.47), while the number of previous relapses was 3.74 (+/- 3.88).

Ninety-one percent of the patients with UC completed the IBDQ-32 during the active period of the disease. Proctitis was present in 2.94% of the cases (3 patients), left-colitis in 71.1% (74 patients), and pancolitis in 26% (27 patients) of the cases. A mild activity of the disease was present in 32 patients; 62 presented a moderate activity, while only 3 presented a severe activity.

The IBDQ-32 Score

The QoL score ranged between 90-180. For proctitis: 80-190, for left-colitis: 120-200, and pancolitis 70-160 ($p<0.05$). Patients with severe forms had a lower score (50-140) as compared to the patients in remission (130-180) ($p<0.01$) (tab. I). The number of previous relapses was significantly influenced QoL ($p<0.05$); patients with previous active disease had a lower QoL. An important factor which negatively influenced QoL was also the long course of the disease, the results showing an average of 29.3 months ($p<0.05$) of disease evolution.

Age, sex distribution, smoker/non-smoker status and the living area (urban/rural) have not shown significant statistical differences. Also, the extension of the lesions has not influenced significantly the statistics regarding the QoL (tab. II).

DISCUSSION

The QoL evaluation in inflammatory bowel disease has become a primary concern and a major objective in recent studies. It serves to appreciate the efficiency of the treatment, helps describe the nature and gravity of the disease and also to assess the prognostic.

IBD has a negative impact on all aspects concerning QoL. The emotional behaviour is mainly disturbed, triggering the development of depression and anxiety during and after the active disease periods (6, 7).

The present study identifies a group with an altered QoL: a long period evolving disease, with an early age debut, with frequent, severe and extended activity periods that would gain benefit after psychiatric counseling.

The importance of the HRQoL is thus confirmed in IBD patients, especially in those with UC. Our results are similar to other studies in which the same test or different HRQoL tests were applied.

An USA study established that the main concern in patients with IBD is related to the doubtful disease progression, the drugs side effects, the impact of the disease on the energy level, the risk of surgical correction, the possibility of a colostomy, the fear of being a "burden" for others and the risk of possible neoplasia. The group of women, also preoccupied with the physical aspects, and younger people were interested in how the disease will influence their sex life (8). In general, women manifested concerns and fears during the active period of the disease (9).

For patients in the active phase, the main attention is directed towards the improvement of the overall status. In order to achieve it, suitable medical and surgical treatment can be used but also through professional psychological and psychiatric support.

Some studies reveal that even patients in remission state may have negatively influenced QoL (10). The main concerns include the side effects of the medication, self esteem and the risk of an evolving neoplasia.

The symptoms frequency is and will remain the main factor to influence QoL. The first diagnostic age doesn't seem to influence HRQoL, but significant inversely proportional correlations with the overall duration of the disease were observed (the longer the progression was, the lower the HRQoL indexes) (11).

Moreover, it has been proven that IBD patients are more likely to develop depression and anxiety as compared with the general population. These findings are associated mostly with the symptoms frequency, the undergoing invalidity and the poor nutritional status (12). The intensity of the psychic disturbance seems to be linked to the severity of the illness but the psychic factors do not seem to have a major influence on the progression of the disease (11).

The overall perception regarding the health status in UC patients is more pessimistic as opposed to the general population as the patients feel more susceptible to the probability of getting sick. They must live with a potentially handicap perspective, the "burden" sensation for others, which may affect in time the QoL and even help develop major psychic illness. They are confronted with everyday stigmatization, fear and repulsion, frequently describing feelings of discomfort and disability. There are also studies proving a decrease in the sexual activity.

CONCLUSIONS

Patients with UC have a significantly influenced QoL as compared to the general population of the same age and sex. A younger age debut, associated morbidity, and medication affect the patients not only physically but they also limit their social life and their educational, professional and emotional activity.

Although HRQoL is influenced in all UC patients, there are few patients with HRQoL similarly to the general population. Identifying the proper factors (social insertion, medication, etc.) might help improve HRQoL in UC patients.

Therefore, IBDQ-32 has proved to be an efficient test in detecting categories with low HRQoL. HRQoL evaluation helps identify patients in need of professional support.

RELATION BETWEEN CLINICAL-BIOLOGICAL ASPECTS AND CD4 LYMPHOCYTE COUNT IN HIV/AIDS PATIENTS WITH NON-TUBERCULOUS PULMONARY INFECTION (Abstract). Pulmonary complications in HIV infection are still an important cause of morbidity and mortality among AIDS patients. An accurate assessment and diagnosis of these patients should include demografic, clinical, and laboratory data associated to the recognition of imaging pattern. When the radiological appearance is atypical and does not suggest pneumonia, the need of interpreting the pulmonary image in relation with HIV viremia level and CD4 lymphocyte count. **Aim**: Analysis of statistical data, diagnosis, course, and particularities of HIV/AIDS cases with non-tuberculous bronchopulmonary infections, and the possible relations between the pulmonary radiological appearance, viremia, and CD4 lymphocyte count. **Material and methods**: Retrospective clinical study of 121 patients with HIV infection and infectious pulmonary disease from Moldova (Romania) diagnosed and treated at HIV-AIDS Regional Centre of the Iasi Clinical Hospital of Infectious Diseases. These patients were followed up in the interval January-December 2011. The studied demographic parameters were: age, gender, area of residence, years of disease. The clinical, laboratory, imaging (pulmonary Xray) data and CD4 lymphocyte count were analysed in dynamics. Data were processed statistically, a direct relation between clinical course and prognosis being found. Patients history, epidemiological history, respiratory symptoms (cough, thoracic pain, dyspnea) associated to the polimorphous clinical picture of HIV infection and the presence of associated comorbidities were recorded. The disease forms found were: lobar pneumonia, acute tracheobronchitis, interstitial pneumonia (non-tuberculous), and bronchopneumonia **Conclusions:** Non-tuberculous bronchopulmonary infectious diseases accounted for a small percentage (13.5%) of the respiratory diseases in HIV/AIDS patients; most infections were found in patients with a CD4 lymphocyte count exceeding 300/mmc; of the clinical forms, acute tracheobronchitis and interstitial pneumonia were the most common; etiological treatment and favorable clinical-biological course were similar to immunocompetent hosts; pneumococci involved in the etiology of bacterial pneumonia in HIV/AIDS patients preserve the same sensitivity as in the seronegative patients. **Key words:** NON-TUBERCULOUS PNEUMONIA, CD4 LYMPHOCYTE COUNT, RESPIRATORY DISEASES IN HIV/AIDS

Cu toate progresele în terapia antiretrovirală, complicațiile pulmonare în infecția HIV rămân o cauză importantă de morbiditate şi mortalitate în rândul pacien-

ților cu boala SIDA. Evaluarea corectă şi diagnosticarea acestora ar trebui să ia în calcul informații demografice, clinice, de laborator, în asociere cu recunoaşterea „pattern-ului" radiologic/tomografic. Aceasta deoarece modificările demografice şi de terapie sunt acompaniate de schimbări ale frecvenței şi etiologiei manifestărilor pulmonare şi implicit ale expresiei radiologice pulmonare.

Sindromul de reconstrucție imună, apărut sub presiunea terapiei antiretrovirale înalt active, ridică probleme de diagnostic diferențial şi dificultăți în decizia de menținere/întrerupere a terapiei antiretrovirale, în lipsa unei bune corelații între clinică, aspectele radiologice şi numărul limfocitelor CD4 (1).

Incidența pneumoniei bacteriene la persoanele infectate cu HIV este de aproximativ 6 ori mai mare ca în populația generală. Pneumoniile şi bronşitele acute sunt cele mai frecvente afecțiuni respiratorii la acești bolnavi în țările dezvoltate, fiind, de obicei, şi prima manifestare clinică a infecției HIV. Mai mult chiar, creşterea recurențelor în cazul pneumoniilor recurente este predictiv pentru scăderea timpului de supraviețuire (2,3). Spectrul etiologic al acestor pneumonii este similar populației generale, doar cei cu imunosupresie avansată putându-se întâlni şi etiologii neobişnuite (*Nocardia asteroides, Bartonella henselae, Bartonella quintana*).

Tuberculoza poate apărea în orice stadiu al infecției HIV, fiind adesea prima manifestare a bolii (reactivarea); în caz de imunosupresie severă (CD4 <200/mm^3), aspectul radiologic poate simula afectul primar TBC.

Majoritatea pneumoniilor sunt determinate de *S. pneumoniae* şi *H. influenzae*, aceiaşi agenți etiologici implicați în patologia infecțiilor pulmonare comunitare. Pneumoniile nosocomiale, frecvent întâlnite la gazdele imunocompetente, sunt cauzate de *S. aureus* şi agenți Gram negativ, în special *P. aeruginosa*, iar rareori poate fi implicată *Legionella pneumophila* şi *Mycoplasma pneumoniae*.

MATERIAL ŞI METODE

S-a realizat un studiu clinic de tip retrospectiv prin urmărirea a 121 de cazuri din Moldova cu infecție HIV şi afectare infecțioasă pulmonară, asistate la Centrul Regional HIV-SIDA din cadrul Spitalului Clinic de Boli Infecțioase Iaşi, în perioada ianuarie - decembrie 2011, diagnosticate şi tratate în cadrul aceluiaşi centru. S-au evaluat vârsta, sexul, mediul de rezidență, anul îmbolnăvirii, datele clinice, de laborator, imagistice (radiografia pulmonară), nivelul viremiei RNA-HIV şi numărul limfocitelor CD4 în dinamică. Datele au fost prelucrate statistic, realizându-se o corelație directă cu evoluția clinică şi prognosticul pacienților.

Au fost definite următoarele criterii clinico – biologice şi radiologice pentru monitorizare:

- debut brutal cu simptome respiratorii traheo-bronşice, cu/fără reactanți de fază acută, cu absența unei imagini radiologice sugestive;
- debut brutal sau insidios, de maxim 14 zile în ambulator, cu simptome respiratorii traheo-bronşice şi imagini radiologice atipice, cu un număr de limfocite CD4 peste 200/mm^3 şi spută negativă pentru BK;
- debut brutal sau insidios, de maxim 14 zile în ambulator, cu simptome respiratorii traheo-bronşice şi imagini radiologice caracteristice de pneumonie lobară;
- fenomene de insuficiență respiratorie acută obiectivate clinic şi prin gazometrie sangvină, cu modificări radiologice pulmo-

nare (bronhopneumonie, infiltrat interstițial).

Între entitățile clinice s-au consemnat: pneumonia lobară, traheobronşita acută, pneumonia interstițială (non tuberculoasă) şi bronhopneumonia.

Alături de acestea s-au luat în considerație includerea în evidență ca seropozitiv HIV şi până la apariția simptomatologiei pulmonare sugestive, tratamentul urmat în momentul internării şi eventualele modificări în terapia antiretrovirală impuse de inițierea tratamentului antiinfecțios.

REZULTATE ŞI DISCUȚII

La finele anului 2011, în evidență activă a Centrului Regional Iaşi se aflau1363 pacienți provenind din 6 județe ale Moldovei, dintre care 1289 (94,6%) aveau peste 20 ani, 41 (3%) avea vârsta între 15 – 19 ani şi 33 (2,4%) aveau vârsta mai mică de 15 ani (tab I).

TABELUL I

Situația pacienților aflați în evidență activă la Centrul Regional Iaşi decembrie 2011

Județul	Grupa de vârstă						Nr. pacienți în evidență activă
	0 – 14 ani		15 -19 ani		> 20 ani

*Pentru valorile mai mici de 10, proporțiile sunt orientative

În anul 2011, la Centrul Regional Iaşi au beneficiat de spitalizare un număr de 895 de pacienți cu infecție HIV/SIDA, reprezentând cazurile nou confirmate şi pacienți cu SIDA stadiul C3, încadrați astfel prin prezența afecțiunilor definitorii şi a numărului limfocitelor CD4, aflați la prima internare pentru afectare infecțioasă respiratorie sau cu pneumonii recurente (tab. II).

Numărul pacienților luați în studiu include cazurile noi declarate şi confirmate respectiv pacienții aflați deja în evidență şi reinternați (unii în repetate rânduri).

TABELUL II

Distribuția pacienților cu SIDA pe stadii evolutive

Stadiu boală	A1	A2	A3	B1	B2	B3	C1	C2	C3
Număr cazuri	27	39	12	11	32	61	18	39	656

Din cei 895 pacienți spitalizați au fost identificate 121 (13,25%) cazuri de infecții respiratorii acute: pneumonie lobară – 34 (28%), traheobronşită acută – 45 (37,2%), pneumonie interstițială (non tuberculoasă) – 40 (33%) şi bronhopneumonie – 2 (1,6%) (fig. 1).

Se observă o proporție relativ redusă (13,5%) a afectării bronho-pulmonare infecțioase netuberculoase în cadrul patologiei generale întâlnite la cele 895 de internări.

Repartiția pe grupuri de vârstă a evidențiat predominanța pacienților de 21 – 30 de ani, urmată de 11 – 20 ani (fig. 2).

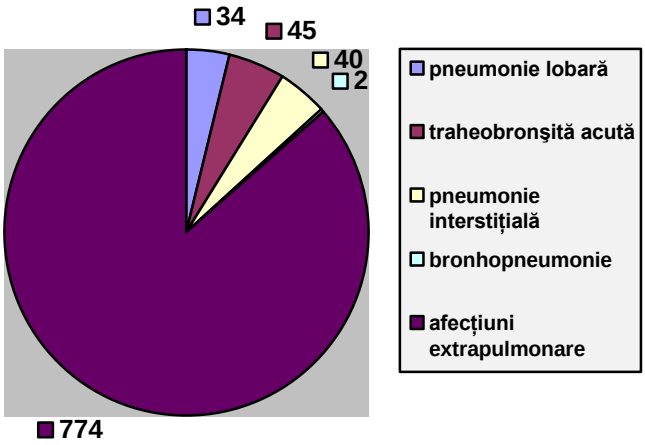

Fig. 1. Proporția afectării infecțioase bronho-pulmonare în cadrul patologiei generale HIV/SIDA la pacienții internați

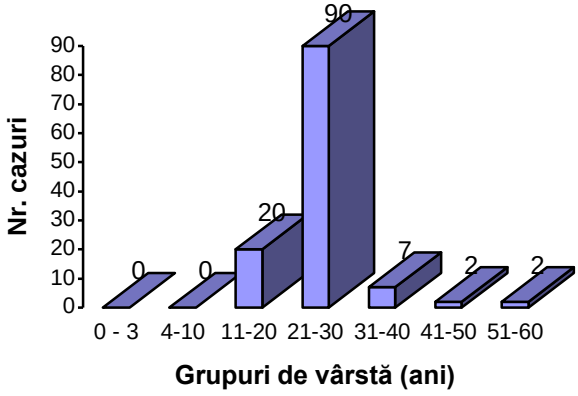

Fig. 2. Distribuția pe grupuri de vârstă a pacienților cu afecțiuni ale aparatului respirator

Am observat o distribuție extrem de polarizată a cazurilor de infecții respiratorii acute la pacienții cu vârste cuprinse între 11 şi 30 de ani, cu un număr foarte redus sau chiar inexistent la celelalte grupuri de vârstă.

Din totalul celor 121 de pacienți, 71 (58,67%) au fost de sex masculin şi 50 (41,32%) feminin.

Un număr de 65 (53,71%) au provenit din mediul rural, faţă de 51 (39,34%) din municipiul Iaşi şi oraşele Paşcani, Târgu – Frumos şi Hîrlău. Un număr de 3 copii erau instituţionalizaţi la Casa de copii Gulliver, iar 2 adulţi proveneau din mediu social defavorizat.

Examenul clinic a evidenţiat simptomatologia respiratorie (tuse, dispnee, dureri toracice) şi manifestările determinate de afecţiunile asociate (tab. III).

Sindromul febril a fost întâlnit în toate cele 121 de cazuri; este o febră persistentă, cu debut cu circa 10 zile anterior spitalizării. Un număr de 40 de pacienţi (33%) au prezentat subfebrilitate (<38^{0}C), iar 81 (66,94%) aveau temperatură între 38 – 40 ^{0}C.

Tusea seacă prelungită a fost prezentă la 66% din cazuri, fără tendinţă la ameliorare. Scăderea ponderală (peste 10%) a fost întâlnită la mai mult de jumătate din lotul studiat. Dispneea de repaus a apărut cu o frecvenţă de 33%, nefiind asociată cu severitatea leziunior pulmonare.

TABELUL III

Simptomele predominante în infecţiile respiratorii non tuberculoase la pacienţii asistaţi pentru SIDA

Simptome	Febră	Tuse seacă	Tuse productivă	Scăderea apetitului	Scăderea ponderală	Dispnee
nr. cazuri	121	80	41	110	90	40
%	100%	66,11%	33,88%	90,90%	74,38%	33%

Ca simptomatologie extrapulmonară în cadrul infecţiei HIV au mai apărut: sindromul diareic (8,3%), adenopatie generalizată (24,8%), greaţă şi vărsături (9,9%), icter sclero-tegumentar moderat (11,6%), tulburări neurologice (encefalopatie intrainfecţioasă şi/sau hipoxică) (16,5%), candidoză oro-faringiană (75%).

Sindromul inflamator a fost prezent la 80 din cei 121 de pacienţi, în proporţie variabilă.

Astfel, VSH-ul s-a situat în intervalul de normalitate la 60 de pacienţi (49,5%), în timp ce creşterea leucocitelor a fost întâlnită în 70 de cazuri (57%). Proteina C reactivă a avut valori de peste 10mg% la 70 pacienţi.

În majoritatea pneumoniilor interstiţiale şi a traheobronşitelor, sindromul inflamator a fost discret sau uşor crescut, în timp ce în cazul pneumoniilor lobare au fost întâlnite valori crescute.

Investigaţii de laborator. Pneumonia bacteriană cu microorganisme încapsulate - *S. pneumoniae* şi *H. influenzae* a reprezentat afecţiunea pulmonară cea mai frecventă la pacienţii HIV/SIDA, ca o posibilă consecinţă a alterării funcţionale a limfocitelor B şi/sau neutrofilelor secundară infecţiei HIV (5). *S. aureus* şi *P. aeruginosa* au fost, de asemenea, implicaţi în patologia respiratorie cu o incidenţă crescută la gazdele imunocompetente, dar pneumonia cu *Pneumocystis jirovecii* a înregistrat valori scăzute.

Din cele 41 prelevate de spută 20 au fost eliminate ca fiind necorespunzătoare, pentru restul s-a calculat scorul Q.

La 5 pacienţi (23,8%) s-a identificat *Streptococcus pneumoniae* care a fost analizat din punct de vedere al rezistenţei la: betalactamine, macrolide, lincosamide, cotrimoxazol, cicline, fenicoli.

Toate cele 5 tulpini au fost sensibile la fluoroquinolone, linezolid, rifampicină şi glicopeptide; un număr de 3 tulpini a prezentat rezistenţă la penicilină şi cicline (tab. IV).

TABELUL IV

Sensibilitatea la antibiotice a tulpinilor de pneumococ identificate

Antibiotic	Sensibilitate	Rezistență
Penicilină		3
Rifampicină	5	
Macrolide	2	3
Vancomicină	5	
Carbapeneme (ertapenem)	5	
Fluoroqiunolone	5	
Clindamicină	5	
Amoxicilină-acid clavulanic	5	

Numărul limfocitelor CD4 şi corelaţia cu aspectul radiologic şi forma clinică: Numărătoarea limfocitelor CD4 a fost efectuată la toţi cei 121 de bolnavi incluşi în lot, rezultând un număr de 90 (74,38%) > 300/mmc, 20 (16,5%) între 200 – 300/mmc şi 11 (9%) < 200/mmc. Toate cazurile de traheobronşite, pneumonii lobare precum şi 29 de pneumonii interstiţiale s-au situat din punct de vedere imunologic în prima şi a doua categorie, în timp ce 11 (9%) cu pneumonie interstiţială au avut CD4 sub 200/mmc (tab. V).

Pneumoniile interstiţiale în cazurile cu un număr al limfocitelor CD4 > 300/mmc au fost interpretate in contextul prezenţei sindromului biologic inflamator ca etiologie mixtă viro – bacteriană, beneficiind de tratament antibiotic (aminopenicilină, cefalosporine, macrolide, fluoroquinolonă), iar cele cu CD4 ≤ 200/mmc au beneficiat suplimentar de asocierea cotrimoxazolului.

TABELUL V

Distribuţia pentru un lot de 121 pacienţi a formelor clinice de boală în relaţie cu numărul limfocitelor CD4

Forma clinică	CD4 > 300/mmc		CD4 200 – 300/mmc		CD4 ≤ 200/mmc	
	Număr	%	Număr	%	Număr	%
Traheobronşită acută	45	37,2 %				
Pneumonie lobară	30	24,8 %	4	3,3 %		
Bronhopneumonie	2	1,65 %				
Pneumonie interstiţială	20	16,5 %	9	7,4 %	11	9 %

CONCLUZII

În anul 2011, la Centrul Regional Iaşi au fost asistaţi 895 pacienţi, din care 121 (13,5%) au prezentat infecţii respiratorii, în majoritate la cei cu un număr al limfocitelor CD4 mai mare de 300/mmc; au predominat traheobronşitele acute şi pneumoniile interstiţiale;

Rezultatele tratamentului etiologic şi evoluţia clinico – biologică au fost favorabile, similar gazdelor imunocompetente, iar numărul limfocitelor CD4 a contribuit la orientarea diagnosticului etiologic şi stabilirea unui tratament de primointenţie;

Tulpinile de pneumococ implicate în etiologia pneumoniilor bacteriene la pacienţii HIV/SIDA au păstrat aceeaşi sensibilitate ca la pacienţii seronegativi.

NOUTĂȚI

GENELE AR PUTEA EXPLICA LEGATURA DINTRE DIABET ŞI BOALA ALZHEIMER

În ultimii ani, a devenit clar faptul că persoanele cu diabet zaharat se confruntă cu o perspectivă de rău augur - un risc mult mai mare de a dezvolta boala Alzheimer. Acum, cercetătorii de la City College din New York (CCNY) au descoperit unul dintre motive. Ei au evidențiat că o singură genă formează o legătură comună între cele două boli şi au descoperit că gena, cunoscută a fi prezentă în multe cazuri de boală Alzheimer, afectează calea de insulină. Perturbarea acestei căi este un semn distinctiv de diabet zaharat. Constatarea ar putea indica o țintă terapeutică pentru ambele boli. Legătura nu este exagerată. Este cunoscut faptul că persoanele cu diabet de tip 2 au un risc crescut de demență. Insulina este implicată în multe procese metabolice, inclusiv în menținerea sănătății sistemului nervos. Deşi cauza bolii Alzheimer este neclară, un criteriu de diagnostic postmortem este prezența de plăci adezive de proteine amiloid în porțiuni ale creierului pacienților distruse de boală. Mutații ale genei umane "precursor de proteine amiloid" (APP) au fost evidențiate în cazurile familiale de Alzheimer. In cadrul studiului, cercetătorii au analizat o proteină numită APL-1, codificată de o genă de la viermele *Caenorhabditis elegans (C. elegans)*, care se întâmplă să fie un perfect stand-in pentru gena boli Alzheimer umane. Ei au descoperit că mutații ale genei de la vierme, echivalent a genei umane APP, au încetinit dezvoltarea acestuia, ceea ce a sugerat că unele căi metabolice au fost întrerupte. Au examinat modul în care echivalentul APP de la vierme modulează diferitele căi metabolice şi au constatat că acesta inhibă calea de insulină. Acest lucru a sugerat faptul că versiunea umană a genei joacă probabil un rol important atât în boala Alzheimer cât şi în diabet. De asemenea, au constatat că mutații suplimentare în calea insulinei au inversat defecte ale mutație APP şi au explicat modul în care aceste gene sunt legate funcțional. Cercetătorii speră că această perspectivă nouă va duce la noi terapii în tratamentul atât al bolii Alzheimer cât şi al diabetului. Rămâne neelucidat modul în care proteinele precursoare ale amiloid şi produsele disocierii sale intersectează calea insulinei (C. Y. Ewald, D. A. Raps, C. Li. APL-1. the Alzheimer's Amyloid Precursor Protein in Caenorhabditis elegans, Modulates Multiple Metabolic Pathways Throughout Development. *Genetics*, 2012; DOI: 10.1534/genetics.112.138768).

PARTICULARITĂȚILE REMODELĂRII CARDIACE ESTIMATE ECOCARDIOGRAFIC LA COPIII CU INSUFICIENȚĂ CARDIACĂ SECUNDARĂ CARDIOPATIILOR CONGENITALE ŞI HIPERTENSIUNE PULMONARĂ

Ina Palii
Institutul de Cercetări Ştiinţifice în Domeniul Ocrotirii Sănătății Mamei şi Copilului,
Departamentul Cardiologie pediatrică
Universitatea de Stat de Medicină şi Farmacie „Nicolae Testemițanu”
Departamentul de Pediatrie

PARTICULARITIES OF THE CARDIAC REMODELLING ECHOCARDIOGRAPHIC ESTIMATED AT CHILDREN WITH HEART FAILURE SECONDARY TO CONGENITAL HEART DISEASES AND PULMONARY HYPERTENSION (Abstract): **The aim** of this study was the determination of the particularities of the cardiac remodeling with echo-cardio graphic methods at patients with chronic heart failure (CHF) secondary to congenital heart diseases and pulmonary arterial hypertension (PAH). **Material and methods:** In the study 204 children were included (average age of 37.1 ± 3.7 months) with CHF secondary to congenital systemic-to-pulmonary shunts (simple, combined and complex) associated with PAH. Depending on the rang of PAH the children were divided into 2 subgroups: IA - 59 patients with CHF and moderate PAH and IB - 145 children with CHF and severe PAH. Using the echocardiography 2D the right and left dimensions of the heart, EF, SF of LV were determined; the Doppler exam - the global function of RV (Tei performance index), systolic and mean pressure in PA. **Results and conclusions:** The particularities of the cardiac remodeling estimated echocardiography with diagnostic value at patients with CHF secondary to congenital shunts complicated with PAH are the following: dilatation of the right cavities of the heart (RVDd and RAD) and of the PA with the tendency of reduction of the LV dimensions, hypertrophy of the anterior wall of the RV, the increasing of the diameter of the fibrosis ring at tricuspid valve, the global dysfunction of RV (Tei index), valvular insufficiency (TVI and PVI), the diminishing of the cardiac index. These parameters were more significant at patients with severe PAH ($p<0.001$), denoting the consequences of the pressure overload on the cardiac remodeling, estimating the level of hemodynamic severity and with certainty can have a special meaning in deciding the therapeutic tactics, prognosis and evolution. **Key words:** HEART FAILURE, CONGENITAL SHUNTS, PULMONARY HYPERTENSION, ECHO-CARDIOGRAPHY, CHILDREN.

Ecocardiografia transtoracică este considerată în prezent cea mai utilizată metodă imagistică non invazivă, standardul de aur în stabilirea şi evaluarea diagnosticului, în aprecierea evoluției, prognosticului şi monitorizarea răspunsului terapeutic la pacienții cu şunturi congenitale sistemico-pulmonare complicate cu insuficiență cardiacă cronică (ICC) şi hipertensiune pulmonară arterială (HTPA) (1). Cateterismul cardiac oferă date hemodinamice mai precise referitor la HTPA şi disfuncția/insuficiența ventriculu-

lui drept (VD), însă investigaţia este o explorare invazivă, cu anumite riscuri, limitată la copiii mici (nou-născuţi şi sugari), scumpă, accesibilă doar în centre specializate (1). Ultimele date din literatura contemporană relatează despre reducerea indicaţiilor la cateterism cardiac în cardiologia pediatrică (2). Din aceste considerente se încearcă în prezent, şi noi ne-am alipit altor studii, identificarea metodelor non-invazive, care să permită un diagnostic precoce, cu o mare sensibilitate, să permită determinarea gradului de remodelare cardiacă şi urmărirea evoluţiei, şi să ofere informaţii prognostice, de stratificare a riscului (1).

Evaluarea ecocardiografică a funcţiei VD, fiind un subiect de mare actualitate este dificilă în prezent, deoarece VD are formă de semilună cu suprafaţă endocardică neregulată şi un mecanism complex al contracţiei în contrast cu VS care are formă eliptică şi uşor de evaluat. VD nu se conformează oricărui model geometric clasic şi estimările de volum pot fi imprecise, fapt ce crează o provocare în interpretarea ecocardiografică (3).

În ultimul timp o atenţie deosebită se acordă evaluării funcţiei globale a VD apreciată prin indicele de performanţă miocardică (IPM) sau indicele Tei, determinat cu ajutorul examenului Doppler (4). El se bazează pe măsurările intervalelor de timp Doppler derivate pe perioada ciclului cardiac, tehnica nefiind limitată de către geometria VD la fel ca alte metode. Acest indice a fost validat în cardiopatiile congenitale, HTP idiopatică, maladiile pulmonare cronice şi alte patologii (5,6).

După datele unor autori evaluarea dimensiunilor VD, atriului drept (AD) şi a prezenţei lichidului în pericard este necesară, constituind factori de prognostic importanţi pentru pacienţii cu HTPA şi IC de dreapta (7,8).

Studiile recente ce vizează estimarea consecinţelor supraîncărcării de volum şi de presiune asupra remodelării cardiace, determinarea performanţei miocardului VD la copiii cu cardiopatii congenitale şi HTPA sunt limitate.

Lucrarea noastră a avut drept scop aprecierea particularităţilor remodelării cardiace prin metode ecocardiografice la pacienţii cu ICC secundară cardiopatiilor congenitale şi HTPA.

MATERIAL ŞI METODE

În studiu au fost incluşi 204 copii (vârsta medie 37,1±3,7 luni) cu ICC secundară şunturilor congenitale sistemico-pulmonare (simple, combinate şi complexe) asociate cu HTPA. În funcţie de gradul HTPA, pacienţii studiului au fost divizaţi în două subloturi: sublotul IA - 59 de copii cu ICC şi grad moderat de HTPA (vârsta medie 52,3±7,4 luni) şi sublotul IB - 145 de copii cu ICC şi HTPA grad sever (vârsta medie 30,9±4,2 luni) (PsAP >70% sau 2/3 din cea sistemică).

Examenul a fost efectuat la ecocardiograful Esaote My Lab 50 (2007) în regim M, 2D, Doppler continuu, Doppler pulsatil, Doppler color şi la aparatul SIEMENS-2007. Ecocardiografia 2D a permis determinarea următorilor indici: dimensiunile cavităţilor drepte ale cordului - AD şi diametrul transversal al VD, a arterei pulmonare (AP) şi a ramurilor sale, grosimea peretelui anterior al VD în diastolă (PAVDd), mişcarea septului interventricular (SIV), prezenţa lichidului în pericard. Au fost apreciate şi dimensiunile ventriculului stâng (VS): diametrul telesistolic (DTS)VS, telediastolic (DTD)VS, cel antero-posterior al atriului stâng (DAS), de asemenea, au fost calculate valorile FE, FS

a VS, fiind comparate cu valorile normale de referință după Kampmann C, 2000 (9).

Funcția globală a VD, IPM sau indicele Tei s-a evaluat cu ajutorul examenului Doppler şi calculat prin raportul dintre timpul contracției isovolumice (TCIV) şi a relaxării isovolumice (TRIV) la perioada de ejecție (PEVD) (fig. 1).

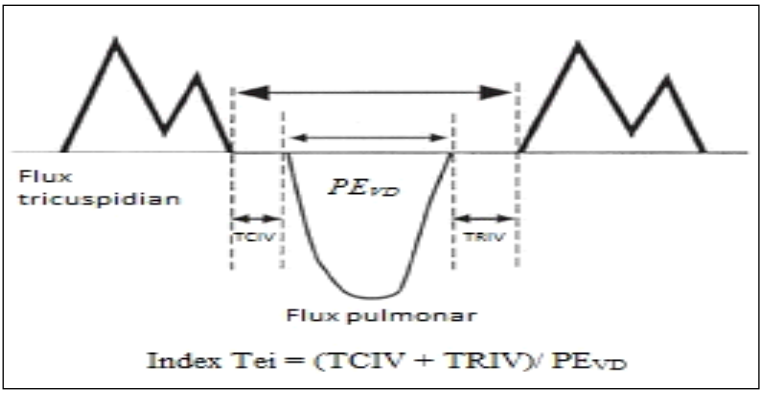

Fig. 1. Metoda de apreciere a indicelui Tei a ventriculului drept (după: 4)

Presiunea sistolică în AP (PsAP) a fost determinată prin măsurarea velocității maxime (V) a jetului de insuficiență tricuspidiană (determinându-se şi gradul de ITr), aplicând ecuația Bernouli: PsVD = $4V_{RTmax}^2$ + PrAD. Presiunea în AD s-a considerat fixă pentru toți pacienții şi egală cu 5 mmHg (conform recomendărilor Ghidului HTP, SEC, 2009). În lipsa unui obstacol la golirea VD, presiuna sistolică din AP este egală cu presiunea sistolică din VD. Presiunea medie în AP (PAPm) am determinat-o prin gradientul protodiastolic maxim dintre AP şi VD pe anvelopa Doppler CW a jetului de insuficiență pulmonară (10). Pentru calculul PAPm am aplicat ecuația Bernoulli simplificată: $4V_{RPmax}^2$ +PrAD. În unele situații am utilizat estimarea PAPm pe baza timpului de ascensiune la AP (TAP), metodă descrisă de Mahan: PAPm = 79 - 0,45 x TAP (11).

Debitul sistemic (Qs) s-a apreciat cu ajutorul integralei vitezei lineare (VTI), suprafața secțiunii transversale a Ao şi FCC, calculând produsul lor, iar raportându-l la suprafața corporală s-a obținut indicele cardiac sistemic (ICs).

Analiza statistică a reziltatelor obținute a fost efectuată cu ajutorul criteriului t-Student de comparare a valorilor medii. Devierea valorii medii a indicelui respectiv față de valoarea martor se consideră statistic semnificativă, dacă probabilitatea erorii nu depăşeşte 5%, deci $p<0,05$.

REZULTATE ŞI DISCUȚII

Ecocardiografia 2D ne-a permis decelarea consecințelor supraîncărcării de volum şi de presiune nu doar a VS studiat de obicei în toate cazurile de IC la adult şi copil (DTDVS, DTSVS, DAS, SIVd) dar mai important a VD, fiind mai rar studiat (tab. I). Dimensiunea diastolică medie a VD (DVDd) a constituit 16,73±0,1 mm în sublotul de pacienți cu HTPA grad sever, față de 15,97±1,0 mm în sublotul cu HTPA grad moderat şi pare a fi fără semnificație statistică ($p>0,05$). Însă dacă ne referim la valori-

le normale corespunzător vârstei şi suprafaţă/corp (după Kampmann, 2000), media normei pentru DVDd în sublotul IB constituie 9,0 mm, iar pentru sublotul IA - 11,0 mm. Astfel, la pacienţii cu HTPA grad sever s-a observat o creştere statistic semnificativă a DVDd - cu 46,2%, faţă de creşterea a DVDd cu 31,1% la pacienţii cu HTPA grad moderat. O altă explicaţie poate fi prevalenţa în sublotul IA a şunturilor combinate cu un defect DSA predominant (n=16) care conduc la dilatarea preponderentă a cavităţilor cardiace drepte. Este bine cunoscut faptul că la supraîncărcare de volum cordul răspunde la stresul hemodinamic prin dilatare de volum, iar la supraîncărcare de presiune - prin hipertrofie; ulterior în evoluţie, odată cu epuizarea mecanismelor compensatorii, survine şi dilatarea cavităţii.

Grosimea peretelui anterior al VD (PAVDd) a constituit 6,51±0,1 mm în sublotul IB *vs* 6,27±0,2 mm în sublotul IA, valorile medii normale pentru aceste subloturi fiind de 2,7 mm şi respectiv 3,0 mm. Deci, se observă o hipertrofie a PAVDd (mecanism compensator local) la pacienţii din lotul cu HTPA severă cu 140,7% faţă de valorile normale şi cu 109% la copiii sublotului cu HTPA moderată, diferenţele fiind semnificative.

TABELUL I

Valorile parametrilor ecocardiografici la copiii cu insuficienţă cardiacă cronică şi hipertensiune pulmonară arterială de diferite grade

Semnele ECO	**Sublot IA ICC cu HTPA grad moderat (n=59)**	**Sublot IB ICC cu HTPA grad sever (n=145)**	**p**
DVDd (mm)	15,97±1,0	16,73±1,0	>0,05
PAVDd (mm)	6,27±0,2	6,51±0,1	>0,05
DITr (mm)	23,16±1,0	24,53±1,0	>0,05
DAD:			
sup-inf (mm)	26,57±1,0	28,37±1,0	>0,05
med-lat (mm)	25,37±1,0	27,22±1,0	>0,05
DAP (mm)	12,95±1,2	16,8±0,4	<0,001
DAP ram. drepte (mm)	10,0±0,9	12,53±0,3	=0,001
Indicele Tei al VD	0,40±0,01	0,47±0,01	<0,001
PsAP (mmHg)	51,31±0,85	75,79±1,28	<0,001
PAPm (mmHg)	37,69±0,48	52,68±0,82	<0,001
DTDVS (mm)	35,28±1,07	34,08±0,91	>0,05
DTSVS (mm)	22,1±0,75	20,42±0,62	>0,05
DAS (mm)	23,08±1,0	23,53±1,0	>0,05
SIVd (mm)	6,48±0,3	6,53±0,1	>0,05
FEVS (%)	69,86±1,0	70,83±1,0	>0,05
FSVS (%)	38,39±1,0	38,82±1,0	>0,05
IC sistemic (l/min/m^2)	2,83±0,15	2,67±0,1	>0,05
IVM (grad)	0,59±0,09	1,3±0,08	<0,001
IVTr (grad)	1,15±0,08	1,87±0,07	<0,001
IVP (grad)	0,85±0,07	1,19±0,05	<0,001

Diametrul inelului fibros la tricuspidă (DITr) a fost de 24,53±1,0 mm la pacienții cu HTPA severă, față de 23,16±1,0 mm la copiii cu HTPA moderată, valorile medii normale în aceste subloturi fiind de 18,0 şi 22,0 mm; înregistrându-se respectiv o majorare a DITr cu 36,3% în sublotul IB, față de 5,3% în sublotul IA (p<0,001).

Dimensiuni crescute ale AD s-au înregistrat în ambele subloturi, dar mai evident au fost la pacienții cu HTPA severă - mărire de 9,2% față de valoarea normală a diametrului superior - inferior al AD şi de 36% al diametrului mediu - lateral, în comparație cu o mărire de 15,4% a dimensiunii medie - laterală a AD la copiii cu HTPA grad moderat. Valorile normale pentru vârstă în loturi sunt: 28 şi 22 mm pentru copiii sublotului IA şi 26 - 20 mm pentru pacienții sublotului IB (după Mayer, Solinger, 2007).

Dimensiunea AP magistrale şi a ramurei drepte au fost statistic semnificativ mai crescute la pacienții cu HTPA grad sever (16,8±0,4 mm şi 12,95±1,2 mm) față de cei cu HTPA moderată (12,95±1,2 mm şi 10,0±0,9 mm) (p<0,001).

PsAP a fost de 75,79±1,28 mmHg la pacienții sublotului IB cu ICC şi HTPA severă, constituind 84,2% din cea sistemică şi 51,31±0,85 mmHg la copiii sublotului IA, reprezentând 54,6% din cea sistemică (p<0,001). De menționat, că TA sistolică la pacienții sublotului IB a fost de 90,1±0,7 iar cea diastolică de 54,4±0,7 mmHg, iar în sublotul IA de 94,3±1,1 şi de respectiv 57,1±1,1 mmHg.

PAPm a fost de 52,68±0,82 mmHg la pacienții sublotului IB, față de 37,69±0,48 mmHg la copiii sublotului IA (p<0,001). Aceste diferențe de presiune în subloturile studiate au şi condus la remodelări variate ale cavităților drepte (dilatare, hipertrofie) şi a AP, dar mai sever exprimate la pacienții cu şunturi congenitale complicate cu HTPA avansată şi disfuncție a VD.

Un aspect particular al valvei pulmonare posterioare datorită valorilor de presiune înaltă, înregistrat prin ecografie mod M, a fost la 109 (76,2%) din pacienții cu HTPA severă față de 21 (35,6%) la copiii cu HTPA moderată (p<0,001).

Indicele de performanță miocardică (parametru cu valoare diagnostică certă) - indicele Tei a VD a fost statistic semnificativ mai crescut la copiii cu HTPA severă - 0,47±0,01 *vs* 0,40±0,01 la pacienții cu HTPA moderată (p<0,001) (fig. 2). Valorile normale citate în literatură pentru vârsta respectivă sunt de la 0,24±0,4 până la 0,28±0,04 (4). Indicele Tei crescut semnifică disfuncția globală a VD, demonstrând consecințele HTPA asupra remodelării cordului drept. Mai multe studii au demonstrat că acest parametru corelează cu FE a VD măsurată prin angiografie cu radionuclizi sau RMN (12,13). Yeo TC şi coaut. încă în anul 1998 au raportat o corelație semnificativă între IPM, simptomele clinice şi supraveţuirea la pacienții cu HTP idiopatică (14).

Noi la fel am observat că acest indice nu depinde de FCC (raportarea TRIV şi TCIV la PE corectează dependența acestora de FCC), de presarcină, de gradul IVTr.

Comparativ au fost estimate şi dimensiunile cavităților cardiace stângi (DTDVS, DTSVS şi DAS), grosimea SIVd, FE a VS şi FS a VS. Datele studiului nostru au relevat dimensiuni mai crescute ale parametrilor VS la pacienții sublotului IA, cu HTPA moderată (DTDVS - 35,28±1,07 şi DTSVS - 22,1±0,75 mm) față de sublotul IB (DTDVS - 34,08±0,91 şi DTSVS - 20,42± 0,62mm), dar fără semnificație statistică (p>0,05). Această particularitate poate fi

explicată prin următoarele: în caz de HTPA severă şi disfuncție VD are loc reducerea volumelor VS cu funcția globală frecvent păstrată; aspectul VS deseori are imagine de literă D. Astfel, o mişcare paradoxală a SIV (de diferită exprimație) cu aplatizarea lui sistolică şi bombarea spre VS a fost observată la 75 (54,7%) din copiii sublotului IB, față de 19 (32,2%) în sublotul IA ($p<0,001$). În ambele subloturi s-a evidențiat hipertrofia SIVd, respectiv 6,53±1,0 şi 6,4±0,3mm ($p>0,05$). DAS a fost crescut față de valorile normale la pacienții cu diferit grad de HTPA, respectiv 23,08±1,0 şi 22,53±1,0 mm, dar fără semnificație statistică ($p>0,05$).

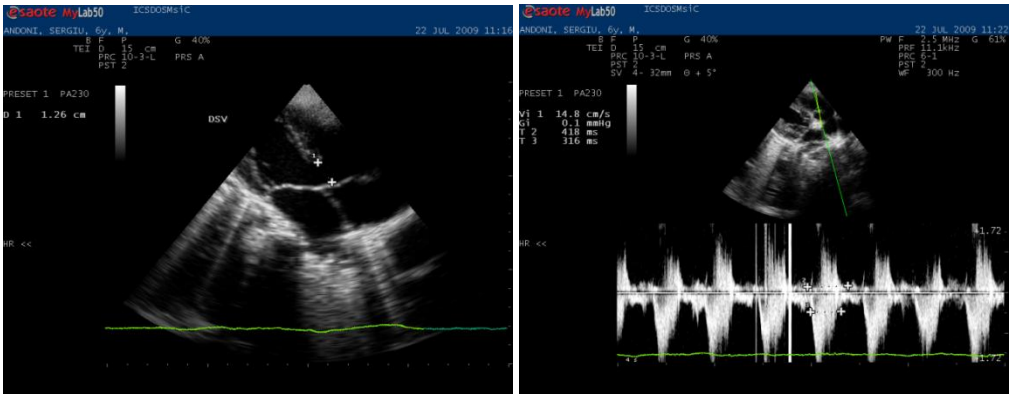

Fig. 2. Determinarea indicelui Tei cu valoare semnificativ crescută (Indice Tei = 0,52) la un băiețel de 6 ani cu DSV membranos de dimensiuni mari, şunt predominant stânga-dreapta şi HTPA severă, disfuncție VD.

FE şi FS a VS în ambele subloturi au înregistrat valori normale: 69,86±1,0% şi 38,39±1,0% la pacienții sublotului IA; 70,83±1,0% şi 38,82±1,0% la cei din sublotul IB ($p>0,05$). Se cunoaşte că determinarea FE pentru estimarea funcției sistolice a VS la pacienții cu cardiopatii congenitale nu este informativă (funcția miocardului este păstrată), valoarea acestui parametru fiind influențat de mulți factori, îndeosebi de mărimea şuntului stânga-dreapta sau de gradul regurgitării atrioventriculare. Astfel, se recomandă la pacienții cu ICC şi şunturi sistemico-pulmonare de a determina DC efectiv, sistemic sau pulmonar. În studiul nostru DC sistemic sau indicele cardiac (IC) a fost diminuat în ambele subloturi, dar mai semnificativ la cei cu ICC şi HTPA severă - 2,67±0,1 față de 2,83±0,15 l/min/m^2. Micşorarea DC este rezultatul necesităților energetice crescute (grație dilatării cavităților) ale miocardului normal la pacienții cu şunturi congenitale.

Majoritatea pacienților cu ICC secundară şunturilor congenitale în asociere cu HTPA au avut insuficiențe valvulare, tricuspide şi pulmonare (IVTr, IVP), dar mai pronunțate au fost în sublotul cu HTPA severă, având semnificație statistică importantă față de sublotul cu HTPA moderată; respectiv gradul IVTr fiind de 1,87±0,07 *vs* 1,15±0,08 ($p<0,001$), iar gradul IVP a fost de 1,19±0,05 *vs* 0,85±0,07 ($p<0,001$). Insuficiențele valvulare estimate denotă remodelarea (dilatarea) cavităților drepte şi prezența cardiomegaliei.

Evidențierea IVTr secundare la aceşti pacienți este posibil legată în primul rând

de dilatarea inelului tricuspidian, modificarea geometriei VD şi deplasarea către apex a cuspelor tricuspidei (15). Gradul de IVM a fost, de asemenea, mai evident la pacienţii cu HTPA severă - 1,3±0,08 faţă de 0,59±0,09 ($p<0,001$).

Prezenţa lichidului pericardic a fost observată în 20 (13,8%) de cazuri doar la copiii cu ICC şi HTPA grad sever. Conform unor studii prezenţa lichidului în pericard constituie un factor de prognostic nefavorabil pentru pacienţii cu HTPA şi IC de dreapta (8).

CONCLUZII

Particularităţile remodelării cardiace estimate la explorările ecocardiografice cu valoare diagnostică la pacienţii cu ICC secundară şunturilor congenitale complicate cu HTPA sunt: dilatarea cavităţilor drepte ale cordului (DVDd şi DAD) şi a AP cu tendinţă de reducere a dimensiunilor VS, hipertrofia PAVDd, majorarea DITr, disfuncţia globală a VD estimată prin indicele de performanţă miocardică Tei, insuficienţele valvulare (IVTr şi IVP), diminuarea DC.

Parametrii sus menţionaţi au fost mai elocvenţi la pacienţii cu ICC şi grad sever al HTPA ce denotă consecinţele supraîncărcării de presiune asupra remodelării cardiace, estimând gradul de severitate hemodinamică.

Indicii remodelării cordului drept din şunturile congenitale complicate cu ICC şi HTPA estimaţi cu siguranţă pot avea o valoare deosebită în deciderea tacticii terapeutice, aprecierea evoluţiei şi a prognosticului acestei suferinţe cardiace la copii.

NOUTĂȚI

ROLUL PROBIOTICELOR ÎN TRATAMENTUL INFECȚIEI CU *HELICOBACTER PYLORI*

Infecția cu *Helicobacter pylori* este un factor major de risc pentru ulcer gastric, ulcer duodenal, limfom gastric si cancer gastric distal. Tratamentul este reprezentat de asocierea a trei antibiotice şi administrarea de probiotice ca terapie adjuvantă. Există mai multe dovezi care susțin rolul probioticelor în reducerea frecvenței efectelor adverse cauzate de tripla asociere terapeutică la care se adaugă articole care afirmă că utilizarea probioticelor îmbunătățește rata de eradicare a infecției. *Lactobacillus gasseri* OLL2716 s-a dovedit eficace atât în suprimarea colonizării stomacului cu *H. pylori* cât şi în reducerea inflamației mucoasei gastrice. Fujimura et all. au raportat că o tulpină *L. gasseri* OLL2716 conținută în iaurt poate coloniza stratul de mucus gastric la pacienții infectați şi poate suprima multiplicarea *H. pylori*. Ei au investigat efectele probiotice ale *L. gasseri* OLL2716 împotriva *H. pylori* tulpina ATCC 43504 prin cocultivare pe agar cu 5% sânge de berbec, la 37°C, în condiții de microaerofilie. După 24 de ore, microscopia electronică din cultura de *H. pylori* cocultivată cu *L. gasseri* OLL2716 evidențiază transformarea cocoidă. Subcultivarea *H. pylori* din nou pe agar sânge de berbec nu a fost urmată de obținerea culturii. Conversia cocoidă şi suprimarea multiplicării *H. pylori* se datorează producerii de dl-acid lactic de către tulpina *L. gasseri* OLL2716. Producerea de dl-acid lactic este caracteristică şi altor specii de *Lactobacillus* (*L. plantarum, L. salivarius*) care pot fi eficiente împotriva infecției cu *H. pylori*. Aceste rezultate susțin utilizarea asocierii de probiotice *L. gasseri* OLL2716 la terapia de eradicare convențională a infecției cu *H. pylori*, mai ales în contextul creşterii incidenței rezistenței la antibiotice a acestor tulpini. (Fujimura S, Watanabe A, Kimura K, Kaji M. Probiotic Mechanism of *Lactobacillus gasseri* OLL2716 Strain against *Helicobacter pylori*. *JClinMicrobiol* 2012; 50(3): 1134–1136).

BOWEL OBSTRUCTION MIMICKING HEPATIC HYDATID CYST RUPTURE. CASE REPORT (Abstract): The hydatid cyst is generated by a parasite which is endemic in Eastern Europe and the Mediterranean area. Rupture of the cyst can trigger an anaphylactic reaction. Therefore, early recognition of rupture symptoms is critical. We here present the case of a patient who knew she had a hepatic hydatid cyst and had refused surgery. She presented to the emergency department for a rapid deterioration of her health status: nausea, vomiting, intense abdominal pains, and visible chills. The ultrasound image suggested a ruptured and infected hepatic hydatid cyst and slightly dilated, hyperkinetic intestinal loops. CT examination revealed bowel obstruction and hydatid cyst appearance unchanged as compared to the previous examination. Symptoms of rupture of a hepatic hydatid cyst include: intense abdominal pain, biliary tree dilation, free fluid in the abdomen, up to fever and hypotension. There are other medical conditions that may simulate rupture of a hydatid cyst. In this case, ultrasound examination revealed the possible cause of deterioration in patient's state of health (hepatic hydatid cyst). The accelerated peristalsis was wrongly interpreted because of cyst rupture, and not a sign of incipient bowel obstruction. It was the CT examination that helped in making the correct diagnosis, bowel obstruction. However, CT scan did not reveal the cause of bowel obstruction but ruled out some possible causes (wall thickening or tumor). The cause of bowel obstruction (adhesions) was established by the correlation of CT findings with medical history and was confirmed surgically and pathologically. **Keywords:** HEPATIC HYDATID CYST, BOWEL OBSTRUCTION, ULTRASONOGRAPHY, COMPUTED TOMOGRAPHY.

The hydatid cyst is generated by a parasite which is endemic in certain areas of Eastern Europe and Mediterranean area. The most frequent locations are liver and lung. Rupture of the cyst can trigger an anaphylactic reaction. Therefore, early recognition of rupture symptoms is critical.

CASE REPORT

A 31-year-old female patient was brought by ambulance to the Emergency Department four months earlier because of intense abdominal pains. She was an unemployed petite white female. Computed tomography (CT) examination performed at that moment described the following lesions:

1. a 48/48/35mm round structure in liver segment 7, well-delineated to the liver, intensely inhomogeneous, with numerous

peripheral and inner calcifications.

2. a 92/80/100 mm inhomogeneous, predominantly liquid structure, with very few tiny peripheral calcifications in liver segments 5 and 8 (fig. 1).

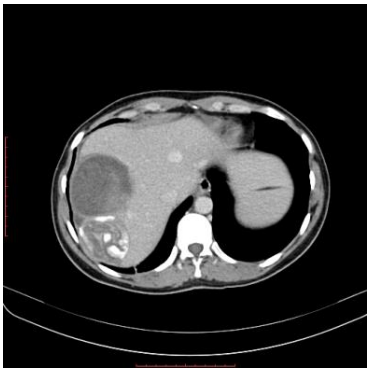

Fig. 1. Hepatic hydatid cysts

Fig. 2. Pus collection under liver

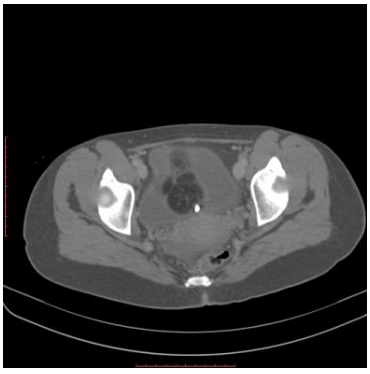

Fig. 3. Ovarian teratoma

3. inhomogeneous lesion of 60/45/80 mm under the liver, with gas bubbles inside, lesion that included the right colic flexure (fig. 2). This structure was considered pus collection from a ruptured hydatid cyst. During surgical intervention it proved to be perforated appendicitis, with pus migrated upwards, towards the liver. Appendicitis was not diagnosed by this CT examination.

4. between the urinary bladder and uterus, an expansive inhomogeneous structure measuring 85/80/85mm, well-delineated, containing fat and two calcifications, diagnosed as teratoma (fig. 3).

In short, CT examination performed at that time revealed: two hepatic hydatid cysts, an abscess (from a perforated appendicitis, with pus migrated under liver), and an ovarian teratoma. The patient underwent appendectomy and right oophorectomy. The patient was discharged 8 days after surgery and was recommended to come back and have the hepatic hydatid cysts removed.

Four months later, the same 31-year-old female patient was brought by ambulance to the emergency department. She had experienced intense abdominal pains for about 14 hours, without any known triggering factor. The patient had a rapid deterioration of her health status: nausea, vomiting, and visible chills. Upon arrival, she also declared she knew she had a hepatic hydatid cyst but had refused surgery. The patient was anxious. She described pain in whole abdomen, but most intense in the right hypochondrium.

Ultrasound examination in the Emergency Department revealed a round structure of about 8 cm x 7 cm, very inhomogeneous in the right lobe of the liver (fig. 4) and slightly hyperkinetic intestinal loops.

No free fluid in the peritoneum and no dilation of the biliary tract were visible. Still, due to the poor state of health of the patient and inhomogeneous appearance of the cyst, the rupture and infection of the hydatid cyst was suspected.

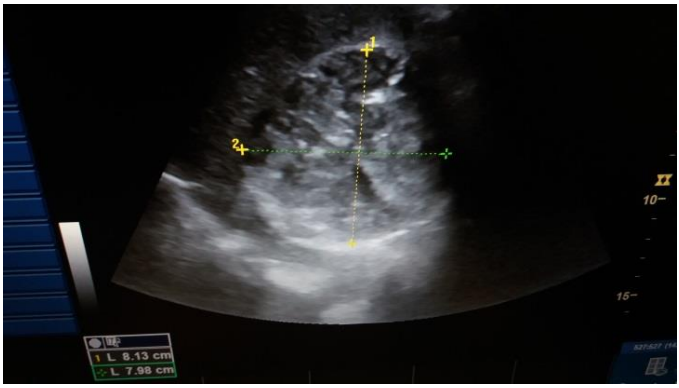

Fig. 4. Hepatic hydatid cyst possibly ruptured

Chest X-ray in the Emergency Department revealed no pulmonary hydatid cyst. Surgical examination revealed a very painful abdomen. The abdomen was moving with breathing and was entirely painful. An abdominal CT was recommended to visualize the hydatid cyst and reveal the possible leakage in the biliary tree or elsewhere.

In the Emergency Department blood was collected. The patient had the following blood values: white blood cells, 10.41 x 10^9 /L; lymphocytes: 14.3%, neutrophils: 81.2%; red blood cells: 4.75 x 10^{12}/L; hemoglobin: 13.8g/dL; hematocrit: 41.3%; Na^+: 138 mmol/L; K^+: 4.1mmol/L; alanine aminotransferase: 18 U/L; aspartate aminotransferase: 19U/L; creatinine: 0.77 mg/dL; serum amylase: 85U/L; glucose: 99 mg/dL.

CT examination revealed that there were two hepatic hydatid cysts, one in segment 7, and a second one in segment 5 and 8, and slightly dilated intrahepatic biliary ducts in segment 8, in contact with the hydatid cyst. Fortunately, images from the previous examination 4 months earlier were found in the CT memory. The radiologist noticed that both hydatid cysts were stationary as compared to the examination four months earlier. The current examination revealed dilated jejunal and ileal loops, up to 35 mm, with air-fluid levels, intense peristalsis, up to the mesogastrium towards the right iliac fossa. No wall thickening was noticed. No tumor was found at that level. Free peritoneal fluid up to 10mm thick could be measured in the pelvic area. No pneumoperitoneum was visible. The CT radiologist concluded that the hepatic hydatid cysts were stationary as compared to the examination four months before, and that there was a bowel obstruction, probably due to adherences, between mesogastrium and right iliac fossa.

The patient was immediately referred to the General Surgery Department, where she was rebalanced with fluids and nonsteroidal anti-inflammatory drugs. That day, the patient did not eat and drink. Gas transit was present. The patient's blood pressure was 100/60 mmHg, with the heart rate 54 beats per minute.

Three days later, the abdominal plain film revealed air-fluid levels in the stomach and small bowel. Blood was collected in the surgery department. The patient had the following blood values: white blood cells: 14.49 x 10^9 /L; lymphocytes: 7.3%, neutrophils: 82.6%. During surgery, numerous dilated small bowel loops were found, with numerous adhesions, and a 10 cm necrotic bowel segment. Adhesiolysis was performed, then segmental enterectomy, followed by enteroenteroanastomosis. Pathological examination of the surgical specimen revealed enter mesenteric infarction.

The next day, gas transit was present. Blood was collected in the Intensive Care Unit, at 9:42 a.m. The patient had the following blood values: white blood cells: 4.97 x 10^9 /L; lymphocytes: 8.9%, neutrophils: 79.6%.

The patient recovered uneventfully and was discharged from hospital with the following recommendations: change the gauze dressing every two days until complete wound healing, avoid physical effort for 3 months, get the metal staples removed two weeks later, wear abdominal belt for a couple of months, follow-up one month later.

DISCUSSION

Though most hydatid cysts can be found in liver and lung, there also are unusual locations, from abdominal wall to heart or hip joint (1). Hydatid cysts are generally single, rarely two or more cysts can be found in the same organ. Our patient was one of the rare cases who had two hepatic hydatid cysts. The hydatid cysts themselves can have unusual aspects (2). Calcification is not synonymous with parasite inactivity (3); it may coexist with still metabolically active cysts.

The severity of hydatid cyst is mainly due to its complications. The most frequent one is rupture into the biliary tract leading to infection, or in the peritoneum (4, 5) and the rarest one is intravascular rupture, considered a lethal emergency. Pulmonary embolism can occur after a fistulization of a hepatic hydatid cyst in the IVC or hepatic veins (6). Symptoms of the rupture of a hepatic hydatid cyst vary from simple discomfort associated with minor signs of allergy to anaphylactic shock (7), and include: intense abdominal pain, dilation of the biliary tree and / or free fluid in the abdomen, up to fever and hypotension. There are other medical conditions which may simulate rupture of a hydatid cyst, like hepatitis (8).

Though the presence of hepatic hydatid cyst can be detected by ultrasonography, detection of dilation of the bile duct or of a small amount of free fluid in the peritoneum is a challenge. On Doppler ultrasound a germinal membrane of the cyst may be found to be extending into the inferior vena cava (9). CT is required to better describe and identify the rupture of a hydatid cyst (10, 11). Magnetic resonance imaging, especially magnetic resonance cholangiopancreatography can be more helpful for the evaluation of dilated intrahepatic bile ducts due to hepatic hydatid cyst rupture (4).

Treatment includes exploratory laparotomy and evacuation of the cyst with deroofing (11). Major hepatectomies (right hepatectomy, left hepatectomy and others) are required for occupation of the entire lobe, severe vascular or biliary involvement, or a combination of the two (12).

In this case, the highly deteriorated health status of the patient was initially believed to be a complication of the known hydatid cyst. The appearance of the hepatic hydatid cysts was not typical on ultrasound

examination, and that is why the right number of the cysts could not be specified, and the numerous calcifications inside the first cyst were wrongly considered as signs of infection. Though neither free fluid in the peritoneum nor dilated biliary ducts were found on ultrasound examination, rupture of the hydatid cyst was suspected, and a CT examination was recommended to identify the point of leakage. It was the CT examination that revealed the cause of the rapid deterioration in health status, bowel obstruction, and the right number of cysts (two). Since neither wall thickening nor tumor was found distally, postoperative adhesions were suspected. Because images at the previous examination were found in the CT memory, the previous and actual appearance of the hepatic hydatid cysts could be compared.

CONCLUSIONS

Bowel occlusion, in the presence of two hydatid cyst, had the same symptoms as a ruptured hydatid cyst: intense abdominal pain, fever, rapid deterioration of the health status and hypotension. Neither free fluid in the abdomen nor dilation of the biliary tree was found upon ultrasound examination. Still, due to the rapid response of radiology and surgery departments, the patient's life could be saved.

METHODS FOR ESTIMATING "DRY WEIGHT" IN HEMODIALYSIS PATIENTS (Abstract): The correct estimation on dry weight is very important in providing effective and safe hemodialysis to end stage renal disease patients. Optimal fluid removal with minimal adverse reactions from the treatment is one goal of hemodialysis treatment. The aim of this article is to discuss different methods of assessing dry weight and to determine their role in the complex fluid management of end-stage renal disease patient. Recent literature describes various methods of determining optimal hydration state, including clinical or paraclinical methods. Each of these methods has their benefits and limitations. Despite the large number of studies conducted on new technologies for determining dry weight, there is a lack of larger, randomized controlled trials to support these methods. Although the successful use of different methods of dry weight assessment is not supported yet by large clinical trials, some evidence is starting to link the use of some methods to improved outcomes (morbidity, mortality) in this population. **Key words**: HEMODIALYSIS, DRY WEIGHT, BLOOD VOLUME, WEIGHT

One advantage of hemodialysis (HD), as a form of renal replacement therapy, is that it can remove both retained fluid and waste products (1). One of the goals is to ensure that fluid and solute removal is optimal and as comfortable to the patient, with minimal or no adverse reaction from the treatment such as hypotension, cramps and dizziness (2).

Dry weight (DW) assessment is crucial in order to achieve an optimal and comfortable fluid removal in the HD patient. This is often difficult to achieve in the hemodialysis setting because of the lack of reliable criteria to determine whether DW has been reached in a particular patient (3), or the lack of evidence to support a particular method of assessment. This is often complicated by the potential for hemodynamic instability during ultrafiltration. Both doctors and nurses play a pivotal role in dry weight assessment (DW), as they are directly involved with patient treatment and could contribute enormously to better patient outcome. The purpose of this article is to discuss the clinical relevance of dry weight assessment and to identify and discuss various methods of assessing dry weight in adult hemodialysis.

The concept of dry weight has always been opened for debate, as clinicians could not agree on how to clinically define dry weight (4). Some clinicians define DW as the weight at the end of the dialysis session at which the patient is more likely to develop symptoms of hypotension (5). For

some (6, 7) the "ideal" dry weight or the "target weight" (8) is the weight the clinicians hope a patient will be at the end of each HD session, without suffering any of the intradialytic complications associated with intravascular volume depletion. DW and solute removal equates to dialysis adequacy (6). Others define DW based on blood pressure (BP) as the parameter, that is, the absence of hypertension and hypotension (9). For some DW is defined as the patient's current body weight in a physiological extracellular volume (ECV) state (10), that is, the ECV is not expanded. To all these definitions, a further statement of "how the patient feels" can be added (4).

The basic concept of fluid transport between the two major fluid compartments in the body, intracellular and extracellular compartments is essential to the understanding of fluid removal and DW assessment (6, 10). The intracellular space holds approximately 23 liters of fluid (for a 70 kg adult), in comparison to 17 liters in the extracellular space, while 5 liters of blood are in the intravascular space (6). In between dialysis, when fluid is not being removed, the intravascular space fills-up to a certain capacity. As the patient continues to consume fluid, excess fluid volume moves into the interstitial space where it can hold as much as 20-40 liters, sometimes known as the third space (6). At this point, gross edema can be observed on the patient.

During hemodialysis, as fluid is removed from the intravascular space, fluid from the interstitial space moves into the intravascular space, known as the plasma refilling rate (PRR) (6, 10). If the PRR is less than the ultrafiltration rate (UFR), that is, fluid in the intravascular space is not being refilled as quickly as it is being taken-off, the patient could suffer from intravascular volume depletion and associated symptoms (11, 12). The most important factors that affect the PRR include: low albumin level, congestive heart failure, reduced plasma osmolality, hypoxemia, ischemia, septicemia, fever, autonomic dysfunction, and ingestion of anti- hypertensive medications (6, 10). In this situation, fluid removal and dry weight assessment is a challenge, as the patient would exhibit signs of fluid overload and yet dialysis staff are unable to further reduce the weight. Further decreasing the weight would result in the patient experiencing intradialytic symptoms, such as hypotension, cramps and dizziness (12).

Optimal and effective hemodialysis is not possible without a correct dry weight assessment. Several studies have been conducted on the effects of inaccurate assessment or estimation of DW. Hypervolemia (fluid overload) is the major risk factor in the development of hypertension, left ventricular hypertrophy, and cardiovascular disease thus affecting the mortality risk of patients on hemodialysis (6). On the other side, hypotension, cramps, and dizziness - signs of hypovolemia - can appear when the DW is set too low (7). Hypovolemia can also result in reduced blood supply to vital organs causing ischemia, consequently contributing to the loss of residual renal function (6).

Death of cardiovascular causes is extremely high in dialysis population, reaching up to 36%. A prospective study of 97 patients on chronic hemodialysis found that a higher interdialytic weight gain (IDWG), of more than 3% body weight, was associated with cardiovascular events: myocardial infarction, congestive heart failure, aortic aneurysm or intracerebral bleeding

(13). Similarly, another study found that high IDWG (>3%) and non-compliance with the treatment, are independent risk factors for higher blood pressure amongst HD patients (14).

The DRIP study, a randomized controlled trial of 150 chronic hemodialysis patients found that DW reduction has a positive effect on blood pressure (9). However, the incidence of intravascular volume depletion, necessitating fluid repletion and ultrafiltration (UF) volume reduction, was commonly seen in the patients receiving the intervention to low DW. In addition, patients in the intervention group had more episodes of clotted access as compared to the control group. This poses the question does reducing DW contributes to clotting of vascular access, despite better BP control? Although this is possible, other factors could have contributed to the higher incidence of clotted access in the intervention group beside DW reduction. For instance, this study has tried to probe DW in the brink of hypovolemia, which could have contributed in the clotting of access. The clotting of access may have resulted due to poor intravascular refilling and not necessarily due to DW reduction. It is possible that the DW could have been reduced efficiently by increasing the dialysis time to provide adequate intravascular refilling time (6). In this instance, blood volume monitoring could be beneficial in evaluating the refilling status on dialysis (11, 15) whilst assessing the DW and BP.

Intradialytic hypotension (IDH) accounts from approximately 20%, according to some authors (6, 16), to 40% of HD complications (12). Inaccurate estimation of DW is one of the causes of IDH. A dry weight set to low will lead to poor PRR and consequently to signs of volume depletion (6, 12, 17). IDH requires immediate medical intervention to prevent further intradialytic complications, such as ischemia and hypoxemia (6). Interventions include administration of normal saline, stopping ultrafiltration (UF) and on occasions, early treatment termination. These lead to an inefficient fluid removal and decrease dialysis dose (18). A survey on the clinical management of hypotension among nurse managers found that the majority of dialysis staff (81%) agreed that frequent occurrence of IDH leads to decreased efficiency of dialysis (17). In addition, although this study found that each IDH episode only took an average of 10,5 minutes to manage, it can be a time-consuming process, and can add additional pressure on dialysis unit staff.

The usual DW assessment is based on trial and error, as patients weight can change periodically and therefore should be assessed on a regular basis (7). Methods of DW assessments include both clinical methods (19) and non-clinical methods, such as inferior vena cava diameter measurement, blood volume monitoring, bioelectrical impedance, and ultrasound lung water assessment (5, 10 14).

Dry weight cannot and should not be assessed in any patient by a single parameter (1). In order to accurately determine patient's DW, a combination of clinical signs and other parameters are often considered. Clinical assessment, that is relatively easy and quick to perform (20), has always been the most widely used by dialysis staff in assessing patient's DW (19). Clinical methods include the measurement of jugular venous pressure (JVP), inspecting for signs of edema (dependent and peripheral), measurement of BP pre and post-dialysis, chest auscultation, assessing skin

turgor and mucous membranes inspection (6, 21). Blood pressure (BP) must be measured sitting and standing, as orthostatic change in BP is a useful diagnostic tool (19). Elevation of the BP, especially if persistent, usually indicates a need to reduce the DW. On the other side, signs of volume depletion, such as persistent low BP, dizziness, cramping, and vomiting may indicate a need to raise the DW (19). Chronic heart failure can be a cause of low BP, and any increase in the DW must be performed with caution in such cases (9). Jugular venous pressure (JVP) is an useful sign, but unfortunately has been neglected by dialysis nurses and physician (10). Elevation in the jugular venous pressure is a useful sign of fluid overload and should be performed before the commencement of hemodialysis. Elevation of the jugular venous pressure during or at the end of hemodialysis may indicate a need for target weight adjustment (10). On the other hand, one must be aware that the mere absence of an elevated jugular venous pressure during hemodialysis or at the end may still be consistent with fluid overload and should not be considered as a sign of reaching the ideal weight. For example, patients with heart failure may not have elevated JVP, but can still be fluid overload (22). The presence of is a reliable sign of excess body water (6) and usually means that DW should be decreased. Serum albumin must also be high enough to facilitate the movement of interstitial fluid back into the circulation (19). Staff must be aware that some patient may still be overloaded in the absence of edema, known as "silent overhydration" (6). Breathlessness is commonly caused by pulmonary edema in this patient population, and is often caused by fluid overload or left heart failure or both (23). Urgent reassessment of DW and of diagnoses other than fluid overload is required (19) so that appropriate treatment could be instituted.

Treatment history should include parameters such as any recent change in target weight and how well the change was tolerated and average IDWG. A record must be also kept of the average pre/post dialysis BP, including postural changes in BP. Other parameters to include in reviewing patient's history include his antihypertensive treatment and whether these drugs are omitted before each dialysis (1). Total proteins, especially albumin, create the oncotic pressure in the intravascular space, and play an important role in the movement of fluid from interstitial tissue to intravascular space (6). In some patients, fluid removal is not well tolerated if the serum albumin is too low (19). The patient may show specific signs/ symptoms as hypotension and cramps, despite still being fluid overloaded (1). It is therefore very important that clinicians review serum albumin level in combination with other clinical signs when assessing DW.

Clinical methods are the most commonly used for DW assessment, although there are some limitations to their use, most specifically physical assessment (5). Heart function or nutritional status can influence fluid overload, while BP can be affected by more than fluid volume. Non-clinical methods that can help in objectively assessing the patients' ideal weight include inferior vena cava diameter measurement, ultrasound lung water assessment, blood volume monitoring and bioeletrical impedance analysis.

Inferior vena cava diameter (IVCD) and collapsibility measurement can evaluate the amount of intravascular volume in HD

patients, that is, it can detect intravascular volume overload or depletion, and correlates well with central venous pressure (19). This procedure is done through echography of the inferior vena cava diameter, measured in supine position during inspiration and expiration (5, 20, 24). It can be useful in dry weight assessment in hemodialysis patients in combination with clinical assessment and has been shown to predict haemodynamic changes during dialysis (20). This method can be unreliable in patients with right sided heart failure, because the IVCD is strongly related to the right atrial pressure (20). In addition, the usefulness of this method is limited by the high cost involved in performing the procedure and the need of exact timing in performing the measurement (10, 20).

In another study on dry weight assessment, Mallamaci et al. reports the use of chest ultrasound to detect pulmonary congestion and potentially guide ultrafiltration and volume removal (25). “Ultrasound lung comets” are ultrasound artifacts generated from the boundary of thickened pulmonary septa and overlying pleura, the ultrasound equivalent of 'Kerley B lines' on a chest roentgenogram, reflecting lung water and elevated left-heart filling pressures. These linear artifacts have been likened to comets by their appearance, and I will personally attest to the relative technical ease of image acquisition for detecting a “lung comet”. Of the 75 hemodialysis patients studied by Mallamaci et al. nearly two-thirds (47 patients) had moderate to severe lung congestion pre-dialysis, and nearly one-third (21 patients) had persistent congestion of the same magnitude post-dialysis. Among the 56 patients who had no symptoms of congestive heart failure pre-dialysis, 57% had ultrasound findings of significant pulmonary congestion. By regression analysis, only left-ventricular ejection fraction was independently associated with excess predialysis lung water. This type of examination can be done quickly, with portable equipment in a dialysis unit, and the same instrumentation can be used for echocardiography, including IVC evaluation.

Blood volume monitoring (BVM) measures the blood density during hemodialysis through an optoelectronic device or ultrasound transmitter (20, 26). As fluid is removed from the vascular space during hemodialysis, excess body water from the interstitial space would transfer into the vascular space (vascular refilling). Certain blood constituents, such as red cells and plasma proteins are unable to leave the intravascular space thus making the intravascular solute mass relatively constant even when there are changes in blood volume due to ultrafiltration or refilling (15). Changes in relative blood volume or blood density, through haematocrit percentage, are then progressively measured during hemodialysis. Clinicians then interpret the relative blood volume and haematocrit in comparison to the UFR throughout the entire dialysis time (27).

Some authors believed that although the BVM is a non-invasive, easy to perform procedure, its main applicability in the clinical setting is to detect blood volume changes during UF and thereby predict end dialytic hypotension (28). But the usefulness of BVM in assessing DW is limited due to the fact that PRR can be influenced by other patient pathologies (i.e. autonomic dysfunction) (10). In addition, other factors such as dialysate sodium can influence the changes in relative blood volume, making BVM limited in the assessment of DW (20).

In another study of 13 chronic HD pa-

tients over 17 weeks, it was found that the relative blood volume and relative blood volume ultrafiltration ratio has considerable differences between the first and third HD sessions, limiting the use of these parameters in preventing hypotension and as a tool in DW assessment (15). However, the results of this study indicate that BVM should be utilized to monitor changes in the patients' relative blood volume every dialysis over a 2-week period. This will then enable clinicians to adequately interpret the results by the end of the 2-week period. In most patients, IDWG is expected to be higher after a 2-day break (of dialysis session) compared to one-day break, hence are unable to reach their DW on their first dialysis day due to limited time (14). If the patient's relative blood volume remains unchanged over the 3 consecutive hemodialysis sessions, that is, the relative blood volume graph is greater than 95% at the end of each dialysis, then the patient still has a lot of interstitial fluid on board, hence DW should be slowly reduced. If patient's relative blood volume continues to decrease towards the end of the week, then the patient is reaching their DW (15).

Lopot et al. argued that BVM can be useful in determining DW by analyzing how patient responds with different UF profile and varying degrees of hydration for each dialysis session (29). It was further stated that for BVM to be used for DW assessment the following methods must be used in the analyses of relative blood volume: (1) a relative blood volume that does not decrease during hemodialysis despite constant UFR, signifies over-hydration hence DW should be reduced; (2) a relative blood volume that decreases during treatment but refilling is seen after UF cessation and patient is symptomatic of intravascular depletion is mainly due to insufficient refilling time. In this instance, DW can still be decrease but dialysis time is increase, to allow sufficient time for refilling of intravascular space; (3) a decreasing relative blood volume during hemodialysis without refilling after UF cessation, and symptom-free dialysis indicates that the patient is on the correct DW and should be maintained (29).

Last but not least, the most promising method seems to be the bioelectrical impedance analysis (BIA). This method assesses the total body water component, that is, extra cellular and intracellular fluid volume. It is very useful in determining fluid status in all body compartments making it an ideal tool in assessing DW (30). This method has been used for the last 30 years for fluid assessment and various methods of bioelectrical impedance analysis have evolved, such as whole body segmental, single frequency and multi-frequency bioelectrical impedance (10).

In a study on 500 hemodialysis patients from 5 centers, Wabel P. et al. used BIA to place the patients in a "hydration plot", according to the overhydration (OH) value and systolic blood pressure (BP). The study illustrated a wide variability of systolic BP regardless of the degree of overhydration, leading to the need for multiple therapeutic approaches in this population. In another study on 370 dialysis patients a cross-sectional analysis using BIA revealed that 26% of patients would benefit from a correction of body weight (31). Another trial used BIA to guide 52 HD patients to normohydration in one year (32). In the hyperhydrated sub-group the fluid overload was reduced by 2 liters and systolic BP by 25 mmHg. In the underhydrated group there was a 73% decrease in intradialytic adverse events without an increase in BP.

In conclusion, both short and long term effects of poor volume control can be prevented by determining the optimal dry weight. New technologies in DW assessment are now available as an added tool for the clinicians to use. According to recent literature these technologies have assisted clinicians in managing effective fluid removal and DW assessment, but the validity and clinical application of these methods is still limited. The reason could be the cost involved or the lack of larger randomized-controlled trials to examine the use in a greater clinical setting. Although the clinical methods are the most commonly used methods in assessing DW, it is important to note that this does not only include physical assessment, but rather a comprehensive review of other parameters such as blood results, medications and treatment history. The increasing use of new technologies, such as BVM, BIA or ultrasound lung water evaluation must be used in combination with clinical methods of DW assessment in preventing the harmful effects of poor fluid management in HD patients.

MYELOID METAPLASIA WITH MYELOFIBROSIS ASSOCIATED WITH ACUTE CORONARY SYNDROME. CASE REPORT (Abstract): A 66-year-old man with myelofibrosis and myeloid metaplasia was admitted to hospital where he was diagnosed with acute coronary syndrome. Percutaneous transluminal coronary recanalization followed by drug-eluting stenting resulted in successful revascularization. Because besides thrombus formation the myeloproliferative syndrome has a potential for bleeding, it is very important to carefully follow-up any clotting abnormality. **Key words**: MYELOFIBROSIS WITH MYELOID METAPLASIA, ACUTE CORONARY SYNDROME, DIAGNOSIS

Sindroamele mieloproliferative includ: trombocitemia esențială, policitemia vera şi leucemia granulocitară cronică care sunt caracterizate prin proliferare excesivă şi diferențiere de-a lungul liniilor megacariocitară, eritroidă şi respectiv mieloidă, precum şi metaplazia mieloidă cu mielofibroză caracterizată prin fibroză excesivă a măduvei hematogene. Cele mai comune cauze de deces asociate sunt: transformarea leucemică, mielofibroza secundară, complicațiile hemoragice şi tromboembolice.

Mecanismul patogenic primar în cazul metaplaziei mieloide cu mielofibroză este reprezentat de un defect la nivelul liniilor de celule stem, ducând la eritropoieză ineficientă, hiperplazia megacariocitelor displazice şi creşterea procentului de granulocite imature. Această mieloproliferare clonală este însoțită de mielofibroză reactivă (fibroza măduvei osoase) şi de hematopoieză extramedulară ineficientă. Suspiciunea diagnostică este ridicată de prezența hematiilor „în lacrimă" şi a precursorilor mieloizi pe frotiul de sânge periferic. Trăsăturile clinice tipice includ: splenomegalie masivă, anemie progresivă şi simptome constituționale (fatigabilitate, subfebrilități, scădere ponderală). Mediana supraviețuirii este situată între trei şi şase ani, cauza principală a decesului fiind transformarea leucemică. În majoritatea studiilor privind factorii prognostici, anemia şi vârsta avansată au fost independent corelate cu supraviețuirea redusă. Alți factori de prognostic negativ sunt: prezența simptomelor catabolice, leucocitoza sau leucopenia, numărul mare de precursori granulocitari, trombocitopenia (<100000/mm³) şi anomaliile cariotipale (1,2).

Incidența reală a evenimentelor tromboembolice la pacienții cu sindroame mieloproliferative este greu de apreciat,

majoritatea studiilor clinice fiind retrospective, pe loturi reduse de pacienți, fără o definire clară a criteriilor clinice şi diagnostice (3). În prezent, terapia mielofibrozei este în principal paliativă.

PREZENTAREA CAZULUI

Pacientul P.G. în vârstă de 66 de ani, cunoscut de aproximativ doi ani cu metaplazie mieloidă cu mielofibroză, supus unei cure cu citarabină în urmă cu 5 luni, fumător, normoponderal, fără antecedente personale sau heredocolaterale de tip cardiovascular, se internează în Unitatea de Terapie Intensivă Coronarieni a Institutului de Boli Cardiovasculare Iaşi pentru dureri retrosternale constrictive, de aproximativ o săptămână, cu caracter progresiv agravat, până la apariția acestora la eforturi minime şi în repaus.

Obiectiv, la internare: tegumente palide; TA=140/80mmHg, AV 73/ min, ritmic fără fenomene stetacustice supraadăugate, fără semne de decompensare cardiovasculară; hepatomegalie nedureroasă la 5 cm sub rebordul costal; splenomegalie gradul III, de consistență dură, neomogenă, ce deformează flancul stâng abdominal.

Dintre rezultatele de laborator reținem: anemie hipocromă, microcitară (Hb 9g%, Ht 28%, GR 5,28 milioane/mm³), regenerativă(R 5,2%), cu fier seric 43µg%, feritină 100ng/ml; număr normal al celorlalte elemente figurate (GA 9370/mm³, trombocite 311000/mm³); IP 76%, INR 1,33 spontan; markeri de citoliză miocardică normali(TnT<0,1ng/ml, CK-MB 10 U/l); funcție renală normală (creatinină serică 0,85mg%, Na 139mmol/l, K 4,3 mmol/l); acid uric 8,9 mg%; fosfataza alcalină 265U/l; LDH 830U/l; BT 1,73 mg% (BD 0.76mg%, BI 0,97 mg%); glicemie 80mg%; proteine serice 57,8g/l.

Frotiul de sânge periferic a evidențiat marcată anizopoikilocitoză, cu microcite, schizocite, hematii ''în lacrimă'', hematii „în țintă", hematii policromatofile, hematii cu inele Cabot, eritroblaşti oxifili 5%; deviere la stânga a seriei leucocitare, până la metamielocit; macroplachete (fig. 1).

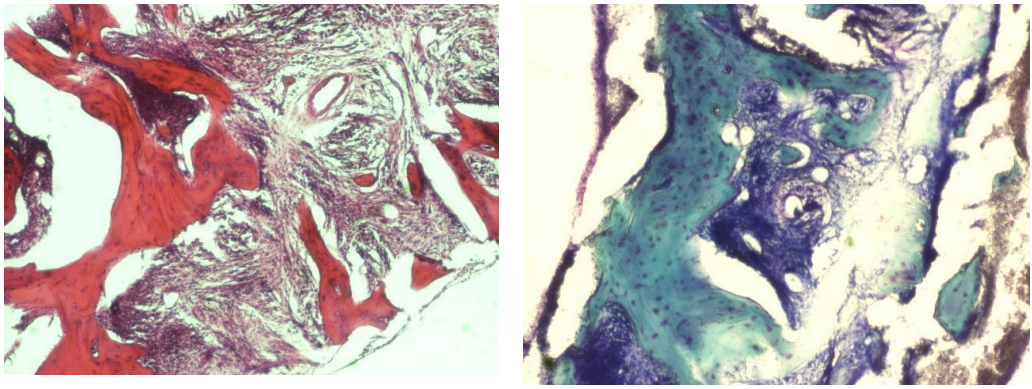

Fig. 1. Coloraţia cu hematoxilin-eozină şi coloraţia May-Grunwald-Giemsa

Electrocardiografic: ritm sinusal 70/min, subdenivelare de segment ST 2 mm, oblic descendentă, urmată de undă T negativă în teritoriul inferior.

Radiologic: cord cu dimensiuni normale (ICT 0,50); plămân fără leziuni evolutive.

Ecocardiografic s-a evidențiat o uşoară hipertrofie concentrică de ventricul stâng,

cu funcţie globală normală (FE 68%), fără tulburări de kinetică segmentară.

Ecografia abdominală confirmă hepatomegalia (lob drept hepatic 173 mm), cu căi biliare principale nedilatate şi splenomegalie masivă (283/130 mm).

S-a iniţiat tratament cu betablocant, heparină, antiagregant plachetar şi nitrat, cu obţinerea controlului simptomatologiei. Având în vedere că anemia severă din cadrul sindromului mieloproliferativ poate fi un factor agravant al anginei, s-a asociat administrarea de eritropoietină şi fier, cu ameliorarea parametrilor hematologici. Ulterior s-a efectuat coronarografia, care a relevat leziuni bicoronariene (artera descendentă anterioară – stenoză ostială 80% şi stenoză 75% în segmentul al doilea, stenoză 80% a arterei coronare drepte în segmentul al doilea). S-a optat pentru angioplastia cu stent acoperit cu everolimus a leziunii ostiale de pe descendenta anterioară, kissing-stenting al originii comune dintre artera descendentă anterioară şi artera circumflexă şi stentare directă a leziunii din segmentul 2 al descendentei anterioare, cu evoluţie ulterioară favorabilă, fără recurenţa anginei la controlul de la o lună postangioplastie.

DISCUŢII

Pacienţii cu sindroame mieloproliferative cronice sunt predispuşi la evenimente trombotice vasculare. Diatezele trombohemoragice caracteristice sindroamelor proliferative prezintă similarităţi calitative: acelaşi tip de diateză hemoragică, o varietate de complicaţii de tip trombotic şi un risc hemostatic care fac evoluţia clinică imprevizibilă. Iniţial acest lucru a fost atribuit numărului crescut de plachete din sângele periferic. Totuşi, numărul evenimentelor trombotice nu este semnificativ mai mare la pacienţii cu trombocitoză; de pildă, în cadrul sindroamelor proliferative, infarctul de miocard complică mai frecvent policitemia vera comparativ cu trombocitemia esenţială, numărul de hematii şi hipervâscozitatea fiind mai degrabă implicate în dezvoltarea trombozei (4,5,6).

Complicaţiile trombo-embolice constituie cea mai importantă cauză de morbiditate şi mortalitate la pacienţii cu osteomielofibroză, cauzând aproximativ o treime dintre decese. Osteomielofibroza a fost considerată o entitate cu risc preponderent hemoragic; recent s-a observat o incidenţă crescută a trombozelor venoase, mai ales în teritoriul portal. Cele mai frecvente complicaţii venoase trombotice sunt tromboza venoasă profundă periferică şi tromboembolismul pulmonar, tromboza de vene hepatice, de venă portă sau de sinusuri venoase cerebrale, producând sindroame clinice caracteristice. Riscul de tromboză arterială este de asemenea înalt, cel mai frecvent fiind afectate arterele membrelor, arterele cerebrale şi mult mai rar arterele coronare sau mezenterice. Sindroamele mieloproliferative sunt caracterizate printr-o lungă perioadă asimptomatică, prediagnostică, când accidentele trombohemoragice pot fi prima manifestare a bolii. Reducerea riscului trombohemoragic pe măsură ce boala evoluează este greu de justificat, emiţându-se ipoteza declinului funcţiei plachetare, cu activare şi degranulare la nivelul spaţiilor din măduva osoasă (2,7,8,9).

Complicaţiile de tip hemoragic sunt mult mai rare, non-fatale, în general implicând vasele mici ale tegumentului şi mucoaselor, putând fi întâlnite şi în prezenţa unui număr normal sau crescut de plachete, fiind cauzate de anomalii calitative plachetare. Tratamentul antiagregant plachetar poate favoriza apariţia hemoragiilor (3).

Literatura citează complicaţii cardio-

vasculare la pacienţii cu sindroame mieloproliferative cronice, de tipul sindroamelor coronariene acute, hipertensiune pulmonară, efuziuni pericardice asimptomatice, tromboză intracardiacă şi chiar leziuni valvulare, acestea din urmă crescând suplimentar riscul ocluziilor vasculare asociate. Relaţia directă dintre sindroamele coronariene acute (pe artere coronare normale sau cu leziuni prezente) şi sindroamele mieloproliferative reprezintă şi astăzi un obiectiv comun al cercetării pentru cardiologi şi hematologi (7,8).

CONCLUZII

Deşi sindroamele coronariene acute sunt complicaţii rare ale metaplaziei mieloide cu mielofibroză, ele trebuie totuşi luate în considerare şi studiate cu atenţie datorită riscului vital crescut pe care îl induc.

O particularitate a cazului o constituie riscul înalt de trombozare precoce a stenturilor. Asocierea tratamentului corect anticoagulant (heparină) şi antiagregant plachetar (aspirină şi clopidogrel) a facilitat evoluţia clinică favorabilă la un pacient predispus trombozelor vasculare. Atragem atenţia însă asupra necesităţii monitorizării atente a anticoagulării şi antiagregării plachetare datorită riscului hemoragic înalt la pacienţii cu sindroame mieloproliferative. Tratamentul cu aspirină în doză mică (100 mg/zi) reduce riscul de tromboză coronariană fără să crească riscul de sângerare (7).

În concluzie, pacientul cu sindrom coronarian acut care asociază metaplazie mieloidă cu mielofibroză necesită o monitorizare atentă a tratamentului anticoagulat şi antiagregant plachetar, alături de corectarea pe cât posibil a parametrilor hematologici şi nu în ultimul rând, controlul factorilor de risc cardiovascular suplimentari.

EVOLUTION OF CLINICAL FEATURES OF SKIN CANCER IN THE ELDERLY. CASE REPORT (Abstract): We present the case of an elderly patient with multiple cardiovascular comorbidities diagnosed with Kaposi sarcoma approximately 10 years ago (the patient having postponed the initiation of the therapeutic protocol) which progressed to dilated cardiomyopathy and procoagulant state because of skin cancer. The onco-geriatric patients represent a distinct category, and as they vary widely in their responses to drugs the individualization of therapy is mandatory and requires the adaptation to the clinical status of each patient.
Keywords: KAPOSI SARCOMA, PRO-COAGULANT STATUS, ONCO-GERIATRICS, CIRS-G SCALE, RISK SCORES.

Kaposi sarcoma (KS) is a multifocal tumor that most commonly manifests in mucocutaneous sites mainly the skin of the lower extremities, face, trunk, genitals and oropharyngeal mucosa (1). KS's relationship with human immunodeficiency virus (HIV) infection is well known and is rare in HIV-negative patients being associated with human herpes virus-8 infection (HHV-8). Based on the clinical ground in which it develops KS is classified into four types: classic or European KS typically appears in middle- or old-aged patients as slow-growing nodules or plaques affecting the oral cavity and skin; endemic or African subtype mainly affects young adults or children and is mostly locally-invasive and/or associated with visceral disease; iatrogenic is mostly observed in organ transplant recipients with immunosuppressive treatment and disappears with the withdrawal of immunosuppression; and AIDS-associated (epidemic KS) which appears in young patients, predominantly homosexual or bisexual men, with multifocal skin lesions (2, 3).

The disease was discovered by the dermatologist Kaposi Moritz in 1872, who

described it as "an idiopathic multiple sarcoma of the skin" (4).

Six cases per million people are reported annually, being the most common neoplasia in HIV-infected patients, and the most aggressive form of the disease (5). Initially, in 1980, the occurrence of KS in AIDS patients suggested that there might be a causal relationship between HIV infection and KS. However, two findings contradicted this theory: HIV proviral DNA was not present in the tumor and not all HIV-positive subjects were equally at risk of developing KS (6).

From a histopathological point of view, there is a double proliferation of fusiform cells and vascular spaces. Being a multifocal affection, it exhibits lesions especially on the lower limbs, with symmetrical disposition in the form of deep, hemispheric, dark red, purple, blue or dark brown dermal nodules (7).

Vascularization in KS takes place prior to the formation of a tumor mass, unlike classical cancers in which angiogenesis begins only after proliferation (8).

CASE REPORT

We present the case of a 79-year-old male, chronic alcohol consumer, former smoker (20 packs-years), known with professional exposure to toxic fumes and contrast temperatures for 20 years, hypertensive for approximately the last 6 years, with maximum blood pressure (BP) of 190/100 mmHg, dyslipidemia, diagnosed 10 years ago with KS (the patient postponing at that time the therapeutic protocol), associating a coronary artery disease in the stage of mechanical (interatrial septal aneurysm) and electrocardiographic (permanent atrial fibrillation) complications. The patient presented to the Emergency Care Unit complaining of dyspnea on low physical exertion, with progressive worsening in the last 3 days, generalized edema and progressive increase in abdominal cavity volume in the last 2 weeks. In the past, chemical conversion was attempted with amiodarone while maintaining sinus rhythm for 2 years after relapse by relative adherence to treatment.

Physical examination revealed that the patient presented anasarca, was in relatively poor general status, afebrile, conscious, normal weight (body mass index BMI=22.5 kg/m^2) and presented cutaneous-mucosal pallor, perioral cyanosis, telangiectasia of the nasal pyramid (fig. 1), purple-colored tumors 0.5-1 cm in diameter at the level of the left lower eyelids (fig. 1), auricular lobes (fig. 2) and abdomen (fig. 3). Moreover, the patient also presented 2 tumors on the tongue (fig. 4) causing swallowing difficulty. Limb examination revealed: keratotic teguments, vascular tumors isolated or in placards on the legs, inferior 1/3 of the forearms and dorsal aspect of the arms, violaceus in color, nonpruritic, superinfected at the level of the right medial malleolus, indurated edema on both lower extremities (fig. 5 and fig. 6). Other findings were: emphysematous thorax, BP=130/90 mmHg, ventricular allure ≈ 120 beats/minute, arrhythmic cardiac sounds, grade 5/6 mitral systolic murmur with radiation to the axilla, grade 4/6 tricuspid systolic murmur, aortic atherosclerosis murmur, turgescent jugular veins. He had increased abdominal volume due to ascitic fluid, sensitive to palpation in the right hypochondrium, liver with sharp inferior border, 3 cm from the costal margin, weakly pulsating leg arteries.

Resting electrocardiogram on admission revealed atrial fibrillation, ventricular rate ≈ 120/minute (asymptomatic patient), micro voltage in the standard and unipolar limb leads, electrical alternation; rS V_2-V_4, mixed terminal phase abnormalities, ventricular extrasystoles some bigeminy (fig.7).

Blood tests revealed: inflammatory syndrome, hypochromic macrocytic anemia syndrome, hepatoprive syndrome, biliary stasis syndrome, hepatic cytolysis syndrome, hyposideremia, hyperuricemia, increased lactate dehydrogenase level, nitrogen retention syndrome. Urinalysis revealed proteinuria and sterile urine culture. The bacteriological analysis of the wound at the right-hand lesions revealed the association of 2 gram-negative bacilli, *Pseudomonas aeruginosa* and *Enterobacter aerogenes*, both susceptible to Levofloxacin. The patient was tested for HIV, the result being negative. Testing for HHV8 was not possible for economic reasons.

Chest X-ray revealed cardiomegaly, right horizontal fissures, aortic knob with calcified contour, accentuated interstitial design (fig. 8). Abdominal and pelvic ultrasound examination documented hepatomegaly with increased reflectivity, inferior vena cava – 26 mm, hepatojugular reflux, presence of the ascitic fluid, gallbladder with edematous walls and without calculi; small size kidneys (right kidney=90 mm, parenchymal index=12 mm, slight cortical echogenicity; left kidney=85 mm, parenchymal index=10 mm, 8 mm lower caliceal stone, echogenic, inhomogeneous renal cortical; prostate=39/40/30 mm with a volume=18 cm^3, inhomogeneous vascular structure. Otherwise, abdominal and pelvic ultrasound did not describe other changes. Echocardiography revealed severely dilated right heart cavities, hypokinetic, severe tricuspid and mitral regurgitation, left ventricular hypertrophy with moderate systolic dysfunction, ejection fraction=40%, associating indirect signs of pulmonary hypertension (fig. 9 and fig. 10).

The initiated complex treatment with anticoagulant, diuretics, coronarodilatator agents, beta blocker, ACE, hepatoprotections, resulted in clinical and biological improvement, with the remission of the phenomena of global cardiac decompensation and improvement of dyspnea. Under antibiotic therapy with new generation fluoroquinolones (according to the antibiogram and recommendations of the infectious physician) and local daily lavatory of skin lesions, the evolution was favorable with the remission of superinfection phenomena. The use of CIRS-G (Cumulative Illness Rating Scale in Geriatric population) lead to the association of oral anticoagulant treatment [score HAS-BLED (Hypertension, Abnormal renal function, Stroke, Bleeding, Labile INR, Elderly, Drugs or alcohol)=6, score $CHAD_2VASC$ (Congestive heart failure, Hypertension, Age ≥ 75 years, Diabetes mellitus, Stroke, Vascular disease, Age 65-74 years, Sex category)=4], but, upon evaluating the therapeutic risks and benefits, it was decided in favor of platelet antiaggregating therapy alone (9). The patient timed antiretroviral therapy and oncology assessment.

The prognosis was poor given patient's non-adherence to treatment, with the possibility of developing other cardiovascular or infectious complications. The association of the cutaneous lesions of Kaposi sarcoma can lead to the occurrence of ulcerations and gangrene and ultimately to amputation.

DISCUSSION

Atrial fibrillation is the most commonly encountered supraventricular arrhythmia in daily practice. The management of atrial fibrillation includes rate-control or rhythm-control associated with antithrombotic medication aimed at reducing morbidity/mortality, the risk of thromboembolic complications and the degradation of ventricular function (10).

Data in the literature support the assumption that the durable effect of HIV infection is due to the consistent correlation between the decrease in the number of $CD4^+$ T cells (under treatment) and the high risk of cardiovascular diseases. The proatherogenic inflammatory status during the therapeutic protocol may be responsible for the suboptimal increase in $CD4^+$ T cells and higher cardiovascular risk.

HAART (highly active antiretroviral therapy) represents an integral part of the treatment, being recommended as the first step. The response to HAART ranges from 20% to 80%, depending on disease severity and immunological status (11).

The impact and consequences upon the quality of life of KS are various; although the most common form is the cutaneous form, and can occur anywhere in the body, it most commonly involves the lymph nodes (the classic form of KS most often

involves the lymph nodes), the respiratory and gastrointestinal tracts (12, 13).

Advanced immune deficiency associated with HIV infection greatly increases the risk of Kaposi sarcoma and the patients treated with antiretrovirals are at higher risk for premature morbidity and mortality compared to non-HIV-infected patients.

CONCLUSIONS

With this case we describe the course and complications of a skin cancer diagnosed 10 years ago, associated with relative adherence to treatment, which progressed to ischemic and valvular dilated cardiomyopathy.

Kaposi sarcoma presented the particularity of a multicentric cutaneous onset, slow course and a predilection for elderly people living in low socioeconomic status areas. Aging is associated with vascular, structural and functional changes, independent of the conventional risk factors.

The risk of bleeding dominates the logic of the clinician in recommending anticoagulant therapy Clinical practice guidelines and prediction scores are not a substitute for clinical judgement.

SPIRAL ENTEROSCOPY – A NOVEL METHOD FOR THE MANAGEMENT OF SMALL BOWEL DISEASES – CASE REPORT AND DESCRIPTION OF TECHNIQUE (Abstract): Small bowel diseases are associated with difficult management. Recently, new methods such as single or double balloon enteroscopy and capsule endoscopy have been implemented for the investigation of small bowel, but none is perfect. Spiral enteroscopy seems to be an alternative primising technique for the diagnosis and therapy of small bowel diseases. We report two cases in which spiral enetroscopy was useful both for diagnosis and therapy. One was the case of a man with repeated digestive bleeding of unknown cause and spiral enteroscopy helped for diagnosis and treatment with argon plasma coagulation of the vascular lesions. The later was a patient with Gartner Syndrome with multiple duodenal and intestinal polyps and spiral enteroscopy allowed small bowel evaluation. In conclusion, this novel method seems to allow a rapid and efficient diagnosis of small bowel diseases. **Key words:** SMALL BOWEL, SPIRAL ENTEROSCOPY, ANGIOECTAZIA, ARGON PLASMA COAGULATION

Small bowel diseases are generally associated with difficult management due to challenging local access both for diagnosis and therapy. Obscure gastrointestinal bleeding, (overt or occult), along with malabsoption, unexplained diarrhea, small bowel radiological abnormalities, small bowel tumors, surveillance of polyposis syndrome, placement of feeding jejunostomy and thermocoagulation of bleeding lesions are all, indications for the investigation of small bowel (1). Recently, new methods such as single or double balloon enteroscopy and capsule endoscopy have been implemented for these diseases (1). However, none of these investigations are perfect and it is still room for improvement. Spiral enteroscopy is an alternative promising technique which seems to have a positive impact in the management of small bowel disease (2).

DESCRIPTION OF THE METHOD

A special design Endo-Ease Discovery SB (DSB) single-use overtube had been developed by Spirus Medical Inc, Stoughton, Mass, USA to assist advancing a normal enteroscope or pediatric colonoscope in the upper gastrointestinal tract. The DSB be has a working length of 130 cm, internal diameter 12.7 mm and external diameter 17.5 mm with superimposed helical spirals 5 mm high at the distal 21 cm. The overtube lightly connects to the enteroscope by a "gentle lock" and may rotate independently from the enteroscope. The enteroscope may advance independently or may perform spiral enteroscopy depending to the unlock or lock position of the spiral overtube (3).

PROCEDURE

The enteroscopy is done with the pa-

Fig. 1. The Endo-Ease Discovery SD (DSB) single-use overtube special designed for spiral enteroscopy

tient under conscious sedation or general anesthesia. The DSB device positioned 25 cm from the tip together with the enteroscope on which it is mounted is advanced to the ligament of Treitz. The spiral device is than unlocked and the enteroscope is advance through DSB over the ligament of Treitz. The DSB is than advanced by clock-wise rotation about 12 cm from the tip and then relocked. From that moment the DSB is turn clock-wise and the small bowel is retracted over the device, allowing progression in the lumen. When this maneuver is not anymore effective, the DSB is unlocked and the enteroscope is advanced until the maximum length of insertion. Further, the DSB is withdrawn by anticlockwise rotation simultaneously with the small bowel examination.

During 2009, a team of gastroenterologist from USA (Dr. P. Akkerman, Dr. M. Ciocirlan) and Paraguay (Dr. D. Cantero) had been performed lectures and practical demonstration in Spiral Endoscopy in Iaşsi. We present two interesting cases performed during the presentations.

Case 1

A 70 yrs old man, from Iasi, was admitted in the Institute of Gastroenterology and Hepatology Iasi for repeated digestive bleeding (melena) of unknown cause. The patient is known with aortic metal prosthesis, receiving oral anticoagulation therapy (acenocumarol) since 1983 and with chronic viral hepatitis C since 2001.

The patient had several episodes of digestive bleeding (melena) since 1984. Some of them were secondary to hemorrhagic gastritis due to anticoagulation and for some episodes, no cause was revealed even after repeated gastrointestinal endoscopy and colonoscopy. However, most of the time the patient had occult blood lost, iron deficiency anaemia and was under iron repletion therapy.

At admission, the physical exam revealed pallor, heart rate 105b/min, blood pressure 100/65, hepatomegaly. Laboratory findings showed: iron deficiency anemia, thrombocytopenia, and hepatocytolysis.

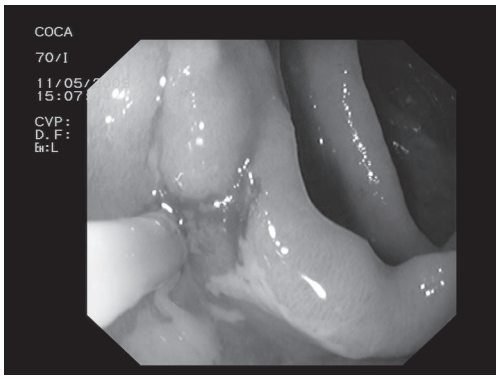
Upper gastrointestinal endoscopy and colonoscopy did not revealed any cause, also at this admission. However, video-capsule endoscopy examination showed multiple angiodisplazia, located probably in the ileum.

Patient underwent exploration with spiral enteroscopy that revealed multiple AVM's in the distal jejunum and proximal ileum and plasma argon coagulation was applied (fig1, 2, 3). Three month follow-up did not reveal any recurrence of bleeding and no anemia.

Case 2

A 25 years old patient known with Gartner Syndrome (Familial Polyposis Coli associated with mandibular osteoma) had recently a total colectomy procedure for removing the colonic polyps. The patient was also known with gastroduodenal polyps. He was admitted in the Institute of Gastroenterology and Hepatology Iasi for the evaluation of the small bowel. A capsule endoscopy procedure for small bowel revealed several small polyps in the duodenum and in the jejunal area.

A spiral enteroscopy procedure was performed in order to evaluate the histology and the possibility of polypectomy. The enteroscopy revealed more than 30 duodenal and jejunal polyps, some $>$ 10 mm in diameter. Polypectomy or biopsies were performed from some of the polyps and the histology showed tubular adenoma low grade dysplasia (fig 4). A spiral enteroscopy through ileostomy



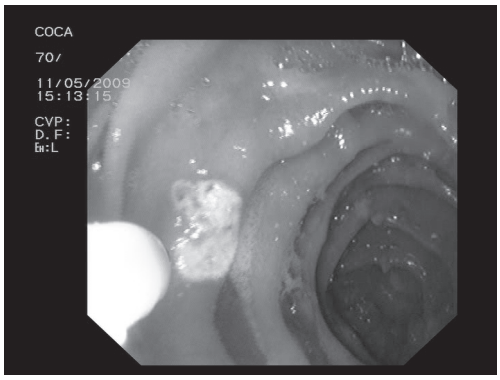


Fig. 2 and **Fig. 3.** Case 1 - Angioectazia of small bowel and thermo-coagulation with plasma argon.

was not done due to the small calibre of the stoma.

DISCUSSION

A patient with small bowel bleeding may be present with melena or hematochezia as overt bleeding or iron deficiency anemia in patients with occult bleeding.

Investigations that allow diagnosis in these cases includes enteroscopy using a colonoscope, sonde enteroscopy (procedures less used nowadays), push enteroscopy or more recent techniques such as single or double balloon enteroscopy, capsule endoscopy. Imaging techniques such as computer tomography angiography/angiography and nuclear scintigraphy are also usefull in detection the site of bleeding however, the later cannot determine the underlying cause.

In our patient, after the exclusion of gastro-duodenal and colonic causes of bleeding, we used the methods available in our unit for the diagnosis and therapy of intestinal bleeding, Capsule endoscopy is now an established technique for detecting obscure intestinal bleeding. The reported diagnostic yield is 63%, superior to push enteroscopy (1,4) and very similar (59.4-80%) to double balloon enteroscopy (42.9-60%) (1,5,6,7). However, capsule endoscopy allows more complete visualization of the small bowel then double balloon enteroscopy (90.6% vs. 62.5%) (6,7). In addition to the diagnostic performance, the non invasive character of capsule endoscopy, allows to be the first investigation to be performed in patients with obscure bleeding (1). There are some concerns on possible severe lesions (tumors) reported to be missed by video-capsule endoscopy and revealed by enteroscopy.

Angioectazia are the single most common cause of bleeding in patients above the age of 50 years (1,8). Thermocoagulation should be used in these patients according to guidelines to treat bleeding and prevent recurrent bleeding. According to location of angioectazia and availability of different enteroscopy techniques (the use of colonoscopy, push enteroscopy, single or double balloon) can be used for the therapy (1).

Patients with polyposis syndromes are at risk of developing small bowel polyps and also complications such as bleeding, small bowel obstruction, intussusceptions or small bowel cancer. Surveillance is recommended for these patients, however the best screening method (capsule endoscopy, enteroscopy, etc.) is yet to be established (1). According to the Spigelman classification for the severity of duodenal polyps, our patient is considered to be stage III (9). The risk for duodenal cancer increases to 36% within 10 years for stage IV patient and the lifetime risk for duodenal cancer is 3-5% (10). Malignancy in the small bowel may also occur but they are unusual. However, severe dif-

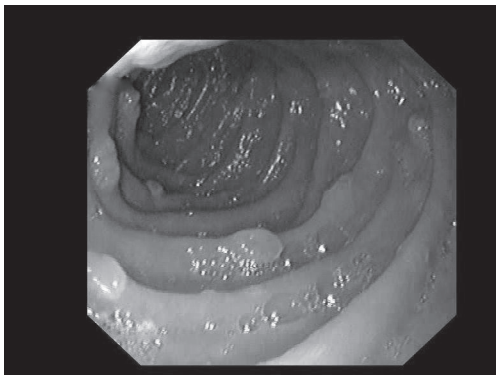

Fig. 4. Case 2 - small bowel polyps

fuse duodenal adenomatosis may require duodenectomy if severe dysplasia is present (10). In our patient, annual surveillance was the option due to low grade dysplasia of the polyps.

Spiral enteroscopy is a novel technique FDA and EC approved which allows along with above mentioned techniques the diagnosis and therapy of small bowel diseases (1, 2). Our case represents the first reported used of spiral enteroscopy in Romania. There are not yet studies comparing spiral enteroscopy with the previous enteroscopic possibilities.

However, published papers suggest that spiral enteroscopy is faster (about half of expected time for double balloon or single balloon techniques). In addition, this method is reasonably safe and the depth of insertion seems to be similar with the double balloon technique. In a recent paper published by Akerman, however on small number of patients (n=27), no major complications were reported. Superficial esophageal mucosal trauma (22% of patients) and sore throat (28%) were the only transient complications reported. In contrast, double balloon enteroscopy, a method on which there are more data, severe complications such as pancreatitis, bleeding and small bowel perforation was reported (3).

In conclusion, spiral enteroscopy is a novel promising method for the investigations of small bowel. However, additional studies are needed to compare spiral enteroscopy with the other diagnostic techniques for small bowel, especially double-balloon enteroscopy.

ANATOMICAL LOCALIZATION OF ATYPICAL MENINGIOMAS: OUR EXPERIENCE ON 81 PATIENTS (Abstract): **Objective:** this study aims to assess a possible relationship between the tumor location and the incidence of atypical meningiomas (AMs). **Material and methods:** from 2010 to 2017, 81 patients with AMs underwent surgical resection. The collected data included: patient age, gender, tumor location, dural venous sinus invasion and tumor laterality (right-left). **Results:** out of the total of 81 patients with AMs, 45 (55.5%) were female patients and 36 (44.5%) were male patients. The male to female ratio was 1:1.3. The mean age of patients who underwent surgery was 62.1 years. There were identified 61 (75.3%) non-skull base meningiomas and 20 (24.6%) skull base meningiomas. Out of the non-skull base meningiomas, the most frequent ones were located at convexity (41.9%) and parasagittal/falcine (32%). Dural venous sinus invasion was reported as present in 18 (22.2%) patients and as absent in 63 (77.7%) patients. **Conclusions:** AMs are more frequently reported in the cerebral convexity than in the skull base. **Keywords:** ATYPICAL MENINGIOMA, SKULL BASE, MENINGIOMA LOCATION, CRANIAL BASE, WHO GRADES.

Meningiomas represent approximately a third out of all primary central nervous system tumors, which makes it the most common brain tumor in adults over 35 years old (1). Out of all these, AMs represent 5-7% of all the meningiomas, according to the 2007 WHO classification (1), with an increasing incidence in recent years (2, 3). At present, AMs account 20% of all meningiomas (4, 5, 6, 7).

Among the multiple prognostic factors of AMs (8) that can predict meningioma grade prior to tissue diagnosis, was also the anatomical localization (9). Several authors noticed the predilection of AMs for cerebral convexity (9, 10, 11).

MATERIAL AND METHODS

We have evaluated 81 patients from the "Professor Dr. N. Oblu" Clinical Emer-

gency Hospital from Iasi, between 2010 and 2016, with histologically proven atypical meningioma (AM) and subsequently underwent craniotomy for resection. We have excluded all patients with neurofibromatosis type 2, multiple meningiomas, and those who had any other intracranial tumor history. The collected data included: gender, age, anatomical localization, dural venous sinus invasion and tumor laterality (right-left) (tab. I). Patient age was defined by the age at the time of surgery. In order to confirm the anatomical localization of AMs, post-contrast T1 magnetic resonance imaging and surgeon's operative note were taken into consideration. Meningiomas were divided into five main categories: (1) convexity, (2) parasagittal/falcine, (3) skull base, (4) posterior fossa and (4) intraventricular. Skull base locations were further stratified as medial and lateral skull base, according to Sade *et al* (10).

RESULTS

Out of the total of 81 patients suffering from AMs, 45 (55.5%) were female patients and 36 (44.5%) were male patients. The male to female ratio was 1:1.3. As for the group distribution, there were: 3 (3.7%) patients <39 years old, 28 (34.5%) patients aged between 40 and 59 years old, 23 (28.3%) patients aged between 60-69 years old and 27 (33.3%) patients older than 69 years. The mean age at surgery was 62.1 years. There were identified 61 (75.3%) non-skull base meningiomas and 20 (24.6%) skull base meningiomas. A more accurate distribution of meningiomas according to localization was performed, as it follows: 34 (41.9%) convexity, 26 (32%) parasagittal/falcine, 13 (16%) skull base (anterior and middle cranial fossa), 7 (8.6%) posterior cranial fossa and 1 (1.2%) intraventricular meningioma. As for the dural venous sinus invasion, this was reported as present in 18 (22.2%) patients and absent in 63 (77.7%) patients. All the patient characteristics are represented in table I and table II.

TABLE I.
Summary of patient characteristics

Characteristic	
No. of patients	81
Age (years)	
Mean	62.1
Median	64
Range	20-85
Age groups	
<39	3 (3.7%)
40-59	28 (34.5%)
60-69	23 (28.3%)
>69	27 (33.3%)
Sex	
Female	45 (55.5%)
Male	36 (44.5%)
Tumor location	
Convexity	34 (41.9%)
Parasagittal/falcine	26 (32%)
Skull base	13 (16%)
Posterior fossa	7 (8.6%)
Intraventricular	1 (1.2%)
Laterality	
Right	32 (39.5%)
Left	28 (34.5%)
Midline	10 (12.3%)
Midline-right	4 (4.9%)
Midline-left	7 (8.6%)
Venous sinus involvement	
yes	18 (22.2%)
no	63 (77.7%)

TABLE II.

Incidence of atypical meningiomas by site of origin

Midline		Lateral			
Tuberculum sellae	1.2% (1)	Orbital roof	1.2% (1)	Convexity	41.9% (34)
Cavernous sinus	4.9 (4)	Orbito-sphenoidal	1.2% (1)	Parasagittal/ falcine	32.0% (26)
Petro clival	1.2% (1)	Lateral / middle sphenoid wing	6.1% (5)	Intraventricular	1.2% (1)
		Lateral tentorial	8.6% (7)		

DISCUSSION

Gender, age. As for the gender, most of the patients were female patients 55.5% (45 cases), while the rest were male patients 44.5% (36 cases). The male to female ratio was 1:1.2. A predominance of males with AM was not found in our study and this gender distribution is different from the ones reported in literature, where grade II meningiomas occur more often in male patients (5). At the same time, other studies have reported a frequency rate of AMs on female patients similar to ours (12, 13). On the other hand, other authors have noticed a gender disparity (14, 15, 16, 17).

The analysis of patient age showed that AMs were diagnosed in the age group with a range between 20 and 85 years (mean age, 62 years). This finding coincides with the data reported so far, which argue that these tumors occur primarily in middle-aged or elderly patients (13, 18). Interestingly enough, in the age group with a range between 40 and 59 years old, there is predominance in women (71.4%) compared to men (28.6%), and a female to male ratio of 2.5:1. In the following age group with a range between 60 and 69 years old, the number of cases in both women and men is similar, with a female to male ratio of 1:1. After the age of 69, AMs are more common in men (59.2%) (fig. 1). This finding can be explained through the sex hormones status in the adult female until menopause and progesterone receptor status, since studies show that grade II or grade III meningiomas have progesterone receptors (19). Also, progesterone receptors play an important role in other neoplasia (20, 21, 22).

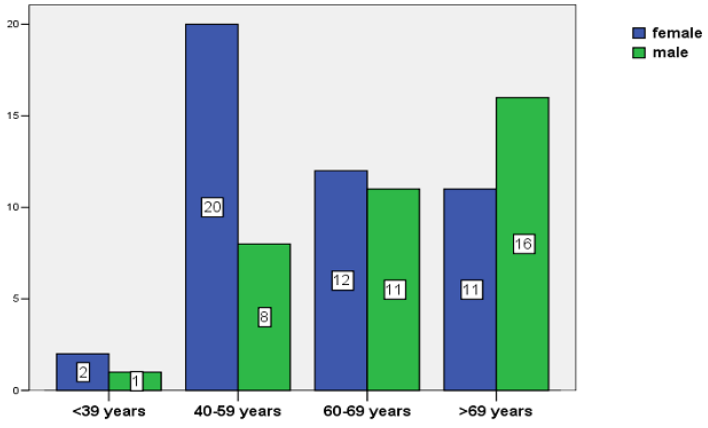

Fig. 1. Distribution by age groups

Tumor location. In our study, we have identified a predominance of AMs for non-skull base locations, in a percentage of 75.3%, compared to skull base meningiomas, which account for 24.6% of the AMs. According to our classification (tab. I), among non-skull base locations, most of the meningiomas were located at brain convexity (41.9%), while the second position was occupied by the parasagittal/falcine location (32%), consistent with studies that show similar percentages (13, 23, 24, 25) (fig. 2). The distribution of anatomical locations of tumors on age groups is similar both in women and men (fig. 3).

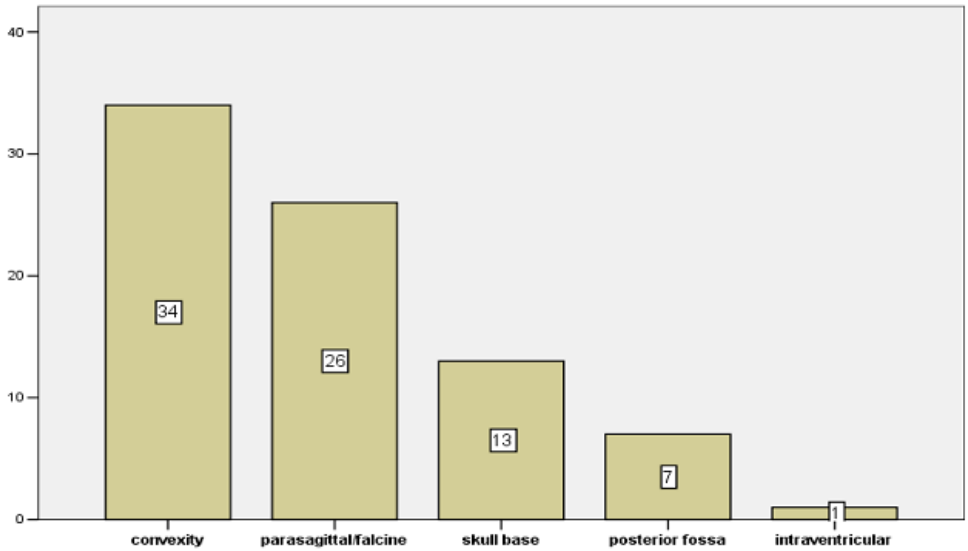

Fig. 2. Incidence of AMs according to anatomical location

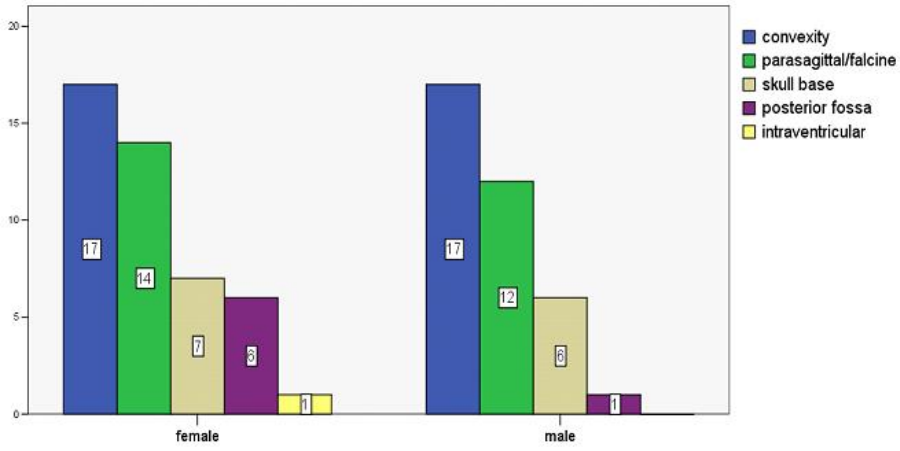

Fig. 3. Incidence of tumor location according to gender

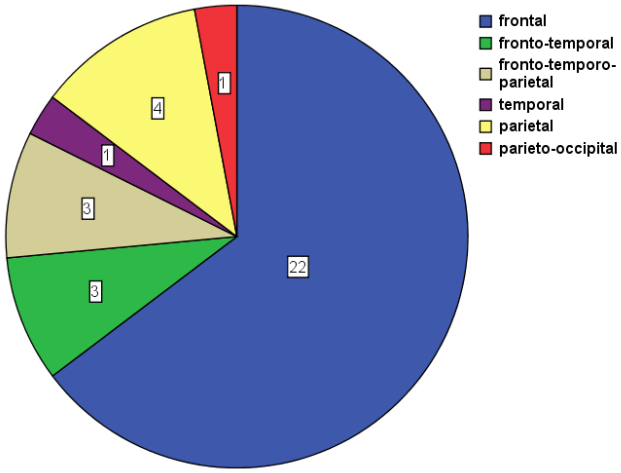

Fig. 4. Incidence of AMs according to anatomical location

Among the first studies on atypical and anaplastic meningiomas with a propensity for cerebral convexity, were those of Mahmood *et al*. and Maier *et al*. (26, 27). In a clinicopathological review of 319 patients, Mahmood *et al.* noticed that most of the atypical and anaplastic meningiomas were located in the cerebral convexities (26). Similarly, Maier *et al.* observed a higher incidence of atypical or malignant meningiomas in falcine or convexity locations in 252 of the patients (27). This preliminary evidence was about to change or at least become a challenge for the traditional notion according to which the histopathological behavior of meningiomas is not at all connected to their localization in the intracranial area (28). Most of the AMs (64.7%, 22 patients) in the brain convexity, were located in the frontal area, with a prevailing occurrence compared to other convexity locations consistent with the studies (29) (fig. 4).

Non-skull base tumors were shown to have an increased risk for grade II or III meningiomas, compared to skull base tumors (9). This disparity can be explained by the distinct embryologic origin of skull-base and non-skull dura. This tissue origin may lead to a propensity for developing different histologic neoplastic subtypes (10, 30, 31). These different subtypes have been associated with different genetic mutations, which could lead to the occurrence of different degrees in the aggressive behavior (32, 33). At the same time, gaining an understanding of these things could lead to the occurrence of specific adjuvant therapies and to the discovery of antiproliferative activity agents against meningioma as well as flavones and flavonols from wine (34, 35). In this regard, medicine faces various legal and ethical issues when it comes to finding the best treatment for the benefit of patients and to respecting their personal values (36, 37) and in which primary concern is the human being (38). Also, adaptation of the patient and his family to the oncological disease is very important (39).

Compared to adult gliomas, there is less available information on the cell origin of

meningiomas or the critical genetic changes that drive tumorigenesis (40). Indeed, gaining an insight into genetic etiology of meningiomas has its roots in inherited cancer predisposition in patients suffering from neurofibromatosis type 2, out of which 50% develop meningiomas (41).

Embryological studies have shown that meninges covering the brainstem may have different origins from those of the lateral skull base and convexities (10). On one hand, the meninges around the brainstem are thought to arise from the cephalic mesoderm, while the telencephalic meninges arise from the neural crest cells (28, 42, 43, 44). Hence, this differential meningeal embryogenesis can result in the predominance of one arachnoid cell type over other certain location, explaining by the aggressive biological behavior of certain meningiomas compared to others, in specific anatomical locations (10).

On the other hand, McGovern *et al.* proved in a study on 216 patients with WHO grade I, II or III, that benign cranial meningiomas arising outside the skull base, are more likely to recur at a higher WHO grade than skull base meningiomas and, moreover, grade I non-skull base meningiomas have a higher rate of cell proliferation than grade I skull base meningiomas. Interestingly enough, in this study, the MIB-1 labelling index of WHO grade I non-skull base meningiomas (2.60%) was significantly higher than that of WHO grade I meningiomas located at the skull base (1.35%). Through these records, the authors suggest that there might be underlying genetic differences in the behavior of non-skull base meningiomas and skull base meningiomas (11).

As for ***skull base meningiomas***, some studies have shown that there is a significantly higher incidence of benign meningiomas in skull base, even if it implies a more benign behavior, compared to non-skull base locations (10, 30). Furthermore, Lee *et al.* proved, in his study on 794 meningiomas of all histologic grades, that meningiomas of the midline/paramedian skull base were predominantly of grade I, namely, of meningothelial histological subtype, with percentages of 83.3-97.3% out of all the meningiomas located in the: cavernous sinus, clinoid process, optic sheath (30), with distorting the anterior visual pathways (45, 46).

Sade *et al.* suggests another explanation for the decreased incidence of malignant meningiomas in the skull base (10). He believes that skull base meningiomas have a higher propensity in showing early signs and symptoms, while the tumors are small-shaped, due to their proximity to cranial nerves and brainstem. At the same time, non-skull base meningiomas remain clinically silent and present large-shape tumors when diagnosed. This aspect gives tumor enough time to undergo additional molecular alterations, resulting in a malignant transformation (10), and may be a reasonable explanation for the higher incidence of grade II and III meningiomas in the elderly (47). In addition, studies have shown that meningiomas originating at the convexity carry more chromosomal anomalies than meningiomas originating at the skull base (48).

In terms of laterality, most of meningiomas (39.5%) were located at right convexity, and the rest (34.5%) at left convexity, with a right to left ratio of 1:1.1, with no significant differences. Other studies showed similar results but could not prove that meningiomas differ in right- or left-sided laterality (12, 49, 50).

CONCLUSIONS

Our study has proved the predominance of AMs in the brain convexity, while rarely occurring in the skull base. By this, we join the preexisting literature studies which reached the same conclusion, and we believe that further studies are necessary to help shed light on the role of genetic factors in the reports between anatomic location and tumor grade. This thing would be of great help in developing specific therapies for patients with aggressive meningiomas, especially AMs.

THE UTILITY OF QUANTILFERON.TB GOLD IN CHILDREN TUBERCULOUS MENINGITIS DIAGNOSIS (Abstract) : **Material and methods** : We performed QuantiFERON-TB Gold in Tube (QFT-G) in blood and CSF at 40 children who was diagnosed with TB meningitis and at 39 children with non TB meningitis, admitted between October 2006 and December 2009. **Results** : The CSF analyses were suggestive for TB at 27 patients and only 14 had positive culture. The sensitivity of QFT-G in CSF was 72.72% and 69.44% in blood ; specificity 96.96% in CSF and 89.18% in blood ; the positive predictive value was 96% in CSF and 86.2% in blood ; negative predictive value was 78.04% in CSF and 75% in blood. The sensitivity of TST was 61.76% and specificity 82.05%. The sensitivity of the culture from CSF was only 35%. The sensitivity and specificity of QFT-G was higher than TST and culture and better in CSF than in blood. **Conclusions** : The determination of ă -interferon in serum and CSF is useful diagnostic marker of tuberculosis who could improve the management of TB meningitis. **Key words** : TUBERCULOSIS, MENINGITIS, INTERFERON GAMMA, BLOOD TEST, INTERFERON GAMMA, CHILD

Meningita tuberculoasă (TB) este o boală cu gravitate deosebită, impunând un diagnostic precoce şi o terapie etiologică şi patogenică promptă. În ciuda progreselor realizate în acumularea unor noi mijloace de diagnostic şi terapie patogenică, prognosticul rămâne, în multe cazuri. rezervat, decesul survenind la aproximativ 20-30% din bolnavi. Meningita TB este dificil de diagnosticat la copil datorită debutului adeseori atipic şi lipsei unor metode rapide şi sigure de diagnostic. Cultura pentru BK, considerată "standardul de aur", este pozitivă în LCR într-o proporţie de 12-30% din cazuri, iar rezultatele se obţin în 3-8 săptămâni (1, 2).

Apariţia testelor sangvine *in vitro* care măsoară cantitatea de interferon gamma eliberată de către limfocitele T sensibilizate, QuantiFERON TB Gold, pare a fi promiţătoare pentru diagnosticul precoce al meningitei TB. Performanţele testului la copii şi la pacienţii imunocompromişi nu au fost încă suficient clarificate. De asemenea, nu există încă studii extensive privind eficienţa executării testului din LCR. Scopul studiului a fost de a evalua contribuţia testului QuantiFERON TB Gold (QFT-G) în diagnosticul meningitei TB la copii (3,4,5).

MATERIAL ŞI METODE

Studiul se referă la 79 de copii internaţi, în perioada ianuarie 2006- decembrie 2009, în Secţia Boli Infecţioase Suceava şi în Clinica de Boli Infecţioase Iaşi. Lotul a fost împărţit în doua grupuri : primul a inclus

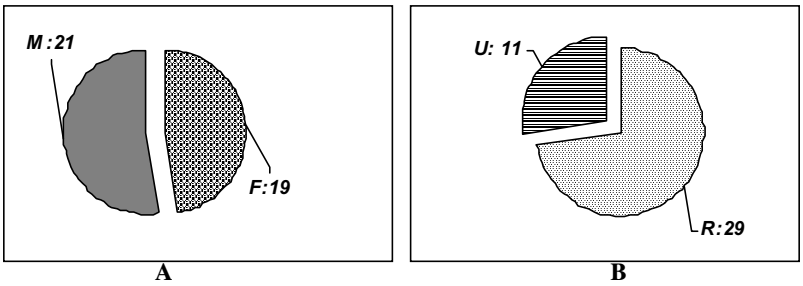

Fig. 1. Repartitia pe sex (A) şi mediul de proveniență (B)

40 de pacienţi diagnosticaţi cu meningita TB, iar al doilea grup martor alcătuit din 39 subiecţi (21- cu meningita virală; 12 – bacteriană; 1 cu toxoplasmoză cerebrală şi 5 fără inflamaţie a meningelui).

Investigaţiile au inclus: hemoleucograma, VSH, ureea, creatinina, glicemia, ionograma, ALAT; examenul LCR (aspect macroscopic, citologie, biochimie, microscopie directă, culturi pe mediul Lowenstein-Jensen); IDR cu 2 unităţi PPD; radiografia toracică; examenul CT cranio-cerebral şi al fundului de ochi; testul QuantiFERON TB Gold în sânge şi LCR, (test elaborat de compania Cellestis), pentru a doza cantitatea de interferon gamma în sângele integral proaspăt, heparinizat, după ce a fost incubat cu o mixtură de proteine sintetice, ESAT-6 şi CFP-10 (6).

Ultima generaţie a testului, QuantiFERON TB Gold in Tube, comportă trei vacutainere (un antigen TB, un control negativ şi unul pozitiv - mitogen). Dozarea interferonului gamma în LCR s-a efectuat folosind kitul QuantiFERON TB Gold cu pachete separate de antigene. După recoltare LCR-ul a fost transvazat într-un microtub uscat steril cu capac. Cu o pipetă sterilă s-a pus câte un ml LCR în minimum 2 godeuri ale unei plăci de culturi celulare pentru a se efectua cel puţin tandemul control negativ - ESAT; dacă a fost posibil s-a adăugat 1 ml şi pentru reacţia cu CFP-10. Deoarece imunocompetenţa pacienţilor a fost stabilită prin folosirea mitogenului în ser, acesta nu a mai fost folosit în cazul LCR-ului. Apoi se adaugă antigenele de stimulare (3 picături/ml), se agită 60 de secunde şi se incubează placa la 37°C. Citirea se face automat cu aparatul de tip ELISA pe baza unui software oferit de Cellestis, obţinând un răspuns calitativ de tip DA/NU. Rezultatele au fost formulate în termenii de negativ, pozitiv sau nedeterminat, considerând valoarea cutt-of de 0,35 UI/ml peste concentraţia controlului negativ.

REZULTATE ŞI DISCUŢII

1. Structura lotului studiat. Lotul de studiu a inclus 40 de pacienţi diagnosticaţi cu meningită TB în perioada 2006-2009, iar cel martor, a cuprins 39 de subiecţi cu meningită non-TB sau fără inflamaţie în LCR, la care s-a efectuat testul QuantiFERON TBGold în sânge şi LCR. Vârsta medie a pacienţilor a fost de 8.85 ani, cu limite între 3 luni - 17 ani, iar raportul dintre sexe a fost, aproximativ, egal (M: F =21: 19), cu diferenţe nesemnificative (p=0,05) pe medii cu creşteri în favoarea mediului urban (fig. 1); cei mai mulţi pacienţi s-au situat în grupul 5-14 ani (fig. 2).

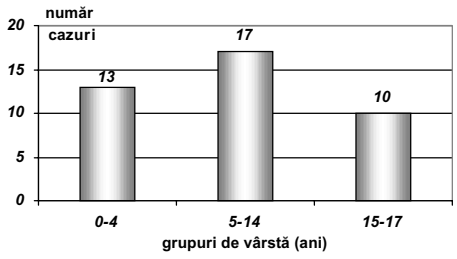

Fig. 2. Repartiţia pe grupuri de vârstă

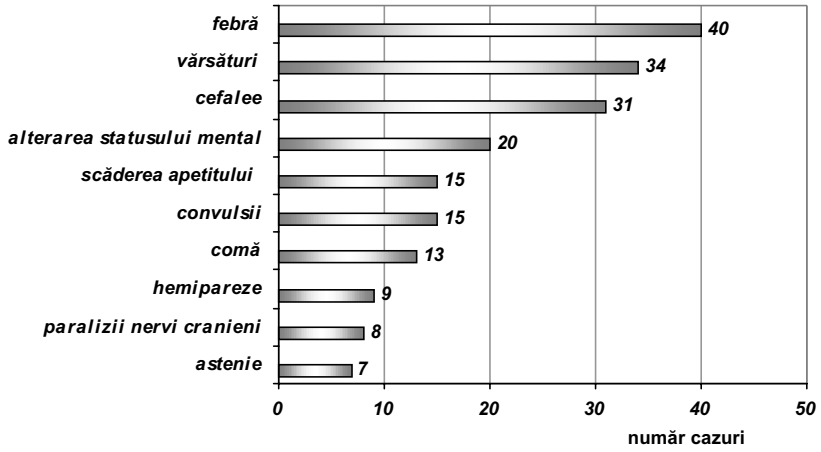

Fig. 3. Semne şi simptome semnificative pentru meningita TB

2. Datele clinice. S-a evidenţiat prezenţa unor semne şi simptome sugestive pentru meningita TB: sindrom febril şi subfebril prelungit (100%); sindrom meningean (77,5%); diminuarea apetitului (37,5%); sindrom encefalitic reprezentat de convulsii (37,5%), alterarea statusului mental, somnolenţă, agitaţie psihomotorie, confuzie (50%), comă (32,5%); paralizii de nervi cranieni (20%); hemipareze (22,5%) (fig. 3).

În unele cazuri simptomele de debut au dus la confuzii cu alte afecţiuni: 9 (22,5%) copii au prezentat tuse şi febră fiind trataţi pentru o afecţiune respiratorie, iar 7 (17,5%) au prezentat dureri abdominale, vărsături, febra, impunând diagnosticul diferenţial cu un abdomen acut chirurgical sau o boală diareica acută; 5 (12,5%) nu prezentau la internare semne de contractură meningeană, acestea fiind semnalate ulterior.

3. Datele epidemiologice. Din anamneza pacienţilor, a rezultat că 24,4% au avut un contact familial de TB şi întregul lot era vaccinat BCG. În ceea ce priveşte factorii favorizanţi s-a remarcat faptul că majoritatea pacienţilor (75,5%) proveneau din mediul rural, având condiţii socio-economice precare.

Din cei 40 de pacienţi cu meningită TB, 6 (15%) erau imunodeprimaţi: 5 cazuri infecţie HIV în stadiul de imunodepresie severă (limfocite CD_4 sub 200 celule/mm^3) şi unul cu leucemie acută limfatică, aflat sub chimioterapie citostatică.

3. Investigaţii paraclinice. Leucocitoza a fost prezentă la internare la 47,5% din cazuri 57,5% au avut un procent crescut de PMN şi 67,5%, VSH-ul a avut valori ridicate; radiografia toracică a fost sugestivă pentru TB pulmonară la 51,1% copii (5 cu formă miliară), 17 opacităţi lobare; o pleurezie TB); examenul CT cranio-cerebral a evidenţiat prezenta hidrocefaliei încă de la internare în 3 cazuri. IDR cu 2 unităţi PPD a fost efectuat la 85% din cei 40 de copii cu meningita TB, fiind excluşi cei şase pacienţi imunodeprimaţi. Citirea IDR-ului s-a efectuat la 72 de ore şi au fost consideraţi pozitivi pacienţii cu indurаţie peste 10 mm. IDR a fost pozitiv în 21 (61,7%) de cazuri. În lotul martor non-TB, IDR-ul a fost efectuat la toţi subiecţii: 32 (82%) au fost negativi şi 7 pozitivi.

Examenul LCR: la 27 (60%) din pacienţi au predominat limfocitele în LCR; glicorahia a fost scăzută la 28 (62,2%), albuminorahia crescută la 35 (77,7%) şi clororurorahia scăzută la 19 (42,2%) subiecţi, aceste date indicând suspiciune de meningita TB (2,3). Examenul microscopic direct nu a evidenţiat prezenţa BAAR la nici unul din pacienţi, iar cultura LCR a evidenţiat

TABELUL I

Rezultatele testului Quantil FERON TB Gold în ser

Rezultat	Meningita TB *		Martori non - TB	
	Nr. cazuri	%	Nr. cazuri	%
Pozitiv	25	62,5	4	10,25
Negativ	11	27,5	33	84,62
Nedeterminat	4	10	2	5,13
Total	**40**	**100**	**39**	**100**

* Pentru valorile mai mici de 10, proporţiile sunt orientative

TABELUL II

Rezultatul testului QuantiFERON TB Gold în LCR

Rezultat	Meningita TB *		Martori non - TB	
	Nr. cazuri	%	Nr. cazuri	%
Pozitiv	24	60	1	2,56
Negativ	9	22,5	32	82,05
Nedeterminat	7	17,5	6	15,39

* Pentru valorile mai mici de 10, proporţiile sunt orientative

TABELUL III

Media variabilelor biochimice din LCR în funcţie de rezultatele testului QuantiFERON TB Gold

	QuantiFERON		Independent t test
	Pozitiv	negativ	
Albuminorahie(g/L)	2,13	1,83	t=-0,45, p=0,69
Glicorahie(g/L)	0,37	0,36	t=0,11, p=0,91
Clorurorahie(g/L)	6,90	6,79	t=-0,87, p=0,39

TABELUL IV

Aspecte comparative ale performanţelor testului QuantiFERON TB Gold, în ser şi LCR

	Comparaţie (%)	
	Ser	LCR
Sensibilitatea	69,44	72,72
Specificitatea	89,18	96,96
Predicţie pozitivă	86,20	96,00
Predicţie negativă	75,00	78,04

TABELUL V

Evaluări comparative privind sensibilitatea şi specificitatea metodelor utilizate în investigaţiile de laborator

Metode	Sensibilitatea	Specificitatea
Cultivare Lowenstein-Jensen	35,00	100,00
IDR 2 unităţi PPD	61,76	82,05
QFT – G ser	69,44	89,18
QFT – G LCR	72,72	96,96

prezenţa *Mycobacterium tuberculosis* în 14 (35%) cazuri. La un copil s-a izolat o tulpină cu rezistenţă la HIN. Intervalul mediu necesar cultivării *M. tuberculosis* a fost de 28,14 zile.

Rezultatele testului *QuantiFeronTB Gold* în ser şi LCR (tab. I, II, III) au evidenţiat diferenţe semnificative statistic ($p=0,05$) între constantele biochimice din LCR în funcţie de rezultatul testului QFT-G in LCR (tab. III). Performanţele testului Quanti-FERON în sânge şi LCR sunt comparabile

cu cele semnalate şi în alte studii. S-a realizat şi o evaluare comparativă privind sensibilitatea si specificitatea diferitelor metode utilizate pentru diagnosticul meningitei TB (6, 7, 8) (Tab. IV, V)

CONCLUZII

Testul QuantiFERON TB.GOLD a permis, coroborat cu datele clinice, epidemiologice şi examenul LCR, un diagnostic rapid (în 48 de ore) a unui număr de 25 cazuri de meningită TB, 12 (48%) dintre ele fiind confirmate şi bacteriologic.

Sensibilitatea şi specificitatea testului QuantiFERON TBGOLD în LCR a fost superioară IDR la tuberculină fiind mai mari în LCR decât în sânge. Performanţele testului QuantiFERON TBGOLD au fost influenţate negativ de terapia antiTB anterioară testării.

Rezultatele negative sau nedeterminate ale QuantiFERON TBGOLD sunt mai frecvente la copiii mici şi în cazul unei reacţii inflamatorii reduse în LCR. Din cei 6 pacienţi imunodeprimaţi diagnosticaţi cu meningita TB, 4 au avut rezultate negative la QFT-G.

Deşi cultura pentru micobacterii rămâne „standardul de aur" în diagnosticul meningitei TB, noile teste imunologice bazate pe eliberarea interferonului gamma par a fi promiţătoare pentru managementul acestei boli, testul QuantiFERON TBGOLD fiind avantajos prin tehnica sa simplă, timpul scurt de realizare şi costurile medii. De aceea, se consideră că testul QuantiFERONTB Gold este o metodă rapidă de diagnostic al meningitei TB la copil, care ar putea îmbunătăţii prognosticul printr-o iniţiere precoce şi adecvată a terapiei TB.

MATERNAL-FETAL ATTACHMENT - UPDATE ON THE ROLE OF THREE DIMENSIONAL, FOUR-DIMENSIONAL AND HD LIVE ULTRASOUND (Abstract): The continuous improvement in obstetrics imagery during the last few decades has contributed in the refining of the prenatal diagnosis but also to enhance the maternal fetal bonding. Two-dimensional (2D) ultrasound images have a positive influence on the attitude of expectant parents toward the pregnancy by enhancing the parental-fetal bond and reducing anxiety in parents. The introduction of three-dimensional (3D) ultrasonography (US) created the opportunity of having a non-invasive technique with easily understood images of the fetus. HD Live technology is a novel US technique that improves the quality of the 3D/4D images. HD Live uses an adjustable light source and software that calculates the propagation of light through surface structures in relation to the direction of light. The HD Live photos are more impressive than the classic 3D pictures, and parents usually request photos. Three-dimensional HD Live enables detailed observation of the fetal external anatomy beginning with the first trimester and doesn't increase significantly the examination time. HD Live may play a role in strengthening this relationship between parents and their future child. **Keywords**: MATERNAL-FETAL ATTACHMENT, HD LIVE ULTRASONOGRAPHY, THREE-DIMENSIONAL, FOUR-DIMENSIONAL ULTRASONOGRAPHY.

The spectacular development in obstetrics imagery during the last few decades has contributed to improving and refining prenatal diagnosis. Previously, what could only be suspected by traditional methods (clinical examination and sometimes medical intuition) became certainty by using ultrasonography.

Maternal-fetal attachment (MFA)

Pregnancy is characterized as a physiologically and biologically interdependent experience, wherein mother and child develop a bond that is qualitatively distinct, unlike any other. The maternal-fetal bond is the strongest bond in humans, and this bond begins often shortly after conception (1). The terms bonding and attachment are used interchangeably in the literature to indicate the feelings that parents have toward their fetus (2). Bonding is the parent's tie to the neonate during the first hours after birth (3); attachment is the relationship between the infant and caregiver that develops during the

first year of life (4). Cranley defined maternal-fetal attachment as: "the extent to which women engage in behaviors that represent affiliation and interaction with the unborn child" (5, 6).

Research on the impact of 2D ultrasound on fetal-parental bonding suggests that these images have a positive influence on the attitude of expectant parents toward the pregnancy by enhancing the parental-fetal bond, reducing anxiety in parents, and increasing awareness on the importance of maintaining maternal health (7, 8).

Three-dimensional and four dimensional (4D) US were first demonstrated nearly 15 years ago but are becoming part of a clinical routine in recent years. The use of 3D and 4D US in obstetrics has many advantages, including providing of an enhanced diagnosis of fetal anomalies, allowing accurate volume measurement of organs with irregular shape, and offering the possibility of storing the volumes (9, 10, 11).

The introduction of 3D US impacted not only the medical community, but also attracted attention from the patients and media because for the first time, technology created the opportunity to have non-invasive, realistic, easily understood images of the fetus. Moreover, the introduction of 4D US into clinical practice allows a better viewing of facial expressions, such as mouth opening, tongue protrusion, yawning, smiling, eye opening and blinking. Visualization of the fetus by the mother may arouse emotions capable of triggering or improving maternal-fetal bonding and may lead to changes in behavior and lifestyle that promote maternal and fetal health (9).

Research on the impact of 3D/4D US on maternal bonding has reported contradictory results. Pretorius et al. analyzed 124 mothers and 65 fathers after 3D US examination using a questionnaire relating to how they felt about their fetus before and after 3D/4D US. They concluded that parents have a change of attitude regarding their fetus after seeing 3D/4D US. (2) Ji et al. compared maternal-fetal bonding between 50 mothers exposed to 2D US only and 50 mothers exposed to both 2D US and 3D US. For all categories of maternal-fetal bonding, patients who had 3D US examinations consistently scored higher than those who had a 2D US examination only (10, 11).

In his study with over 68 pregnant women, Segmen stated that both 2D and 3D US have a positive impact, but 3D US offers no enhanced benefits in comparison to 2D US. (13) Rustico *et al.* conducted a randomized clinical trial with 100 pregnant women during the second trimester to evaluate whether adding 4D US to the conventional 2D US could influence maternal emotional status. No difference in the proportion of women with a positive response to 2D US or 2D US plus 4D US was observed. In addition, when the investigators applied a validated instrument to evaluate maternal-fetal bonding (Maternal Antenatal Attachment Scale) to a subset of 46 patients enrolled in the study, no difference between the two groups in quality and intensity of attachment or global attachment score was identified. (14)

To be relevant and useful for improving fetal-parent attachment, both 2D and 3D images should be as clear and real as possible. With 3D US, technical developments, such as the electronic fetal scalpel, which allows the removal of unwanted information from the volume data set, have been reported to improve the image quality for visualization of the fetal face in approximately 70% of the cases. (15) The latest technological development in US is high-definition HD Live technology and surely

deserves attention regarding MFA.

HD Live technology

HD Live technology is a novel US technique that improves the 3D/4D images. HD Live uses an adjustable light source and software that calculates the propagation of light through surface structures in relation to the direction of light (16). The virtual light source produces selective illumination with the respective shadows created by the structures where the light is reflected (17). This possibility of using HD Live technology to create lighting and shadowing effect increases depth perception. The combination between lights and shadows produces remarkable images that are much more natural than those obtained with classic 3D US. The virtual light can be placed in the front, back or lateral sides, actually where viewing is desired.

HD Live could be used throughout the whole pregnancy. In the first trimester of pregnancy, images that resemble those usually seen in atlases or in media could be very impressive for parents (18, 19). The introduction of 3D/4D US with HD Live in the first trimester of pregnancy has resulted in remarkable progress in ultrasonographic visualization of early embryos and fetuses, and development of new fields of 3D sonoembryology (fig. 1). The HD Live photos are more impressive than the classic 3D pictures, and parents usually request photos or record them. According to Ji et al, mothers exposed to 3D US had a higher tendency to show their US images to other people and to form a mental picture of the baby after the examination than those having only 2D US (82% *vs.* 39%; $p < .001$) (12). Due to natural and artistic image of the fetus, surely the HD Live pictures would be shared with relatives or friends at least as often as classic 3D US.

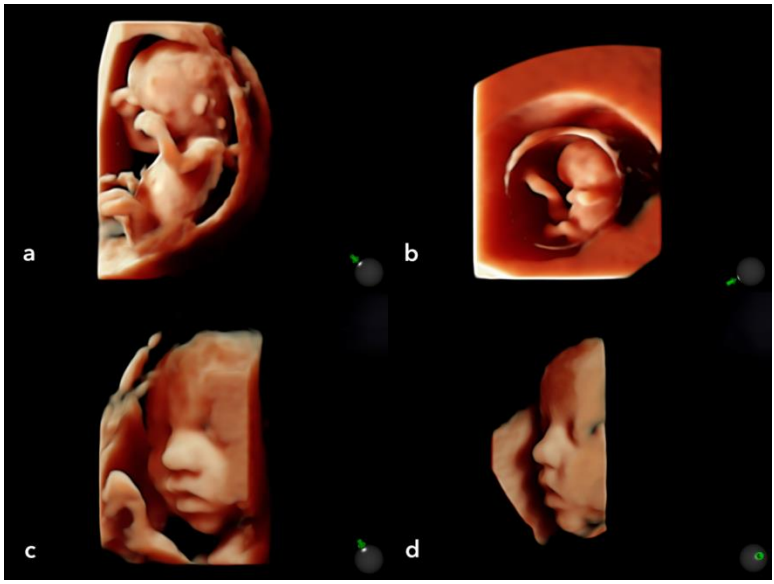

Fig. 1. a. Pregnancy in the first trimester of pregnancy- 12 weeks of amenorrhea.
b. Pregnancy in the first trimester of pregnancy-9 weeks of amenorrhea.
c. Pregnancy in the third trimester of pregnancy- Fetal face.
d. Pregnancy in the third trimester of pregnancy- Fetal profile.

Although the messages from patients are clearly positive, the exact role of HD Live technology in the maternal fetal attachment remains to be established in the future. Because of the more natural and realistic images, it is expected that HD Live will favor and enhance this bonding. Being a new technology, no studies are available yet in the literature to analyze the relationship between the bonding and HD Live. We believe that studies regarding the role of HD Live in improving the fetal-maternal bonding are necessary and will be available in the near future.

Current and future development

Embryonic development is a fascinating area, which might be followed using the ultrasound scanning technique. There has been an immense acceleration in understanding the early human development in the last years due to the newest ultrasound techniques: 3D/4D ultrasound, Doppler ultrasound, tomographic ultrasound images, HD Live (16, 20).

HD Live enables a detailed evaluation of the fetal face from the first trimester and reveals that a small fetus is not more a fetus but a "person" even in the first trimester of pregnancy.

Three-dimensional HD live enables a detailed observation of the embryonic anatomy beginning with the first trimester and in this way, it makes possible to develop new relationships inside the family (19). HD Live represents one of the most promising forms of non-invasive diagnostics in order to study and follow embryo development.

CONCLUSIONS

In actual practice, 3D and 4D US are becoming an important part of state-of-the-art ultrasonographic imaging in obstetrics. HD Live is a new, emerging technology that shows remarkably high-quality images of the embryo and fetus.

Motherhood is an extraordinary opportunity, for both the mother and child, to participate in a relationship that is irreplaceable in value and meaning.

HD Live may play a role in further strengthening this relationship between parents and their future child, but the exact role remains to be established.

SOME EPIDEMIOLOGIC AND FORENSIC MEDICAL ASSESSMENTS ON SUICIDE INCIDENCE AND OTHER CAUSES OF VIOLENT DEATH IN ROMANIA AND IAŞI COUNTY BETWEEN 1997 AND 2006 (Abstract): The study included information collected in the reports of Forensic Medicine Institutes, at the national level, processed and interpreted using epidemiological and biostatistical methods. **Results**: In Romania, at the national level, the annual values of suicide incidence increased from 18 to 30% and in 70-80% of cases, other causes led to violent death (intoxication, precipitation, submersion, burning, cut wounds, shooting a.s.o.). In Iaşi County, the annual values of suicide incidence varied between 1.1 and 2‰ inhabitants, and the main cause was hanging registered in 60.2% of cases in 31-60 age groups, with male predominance. **Conclusion**: Results are useful for the orientation of educational prevention programs. **Key words**: SUICIDE, VIOLENT DEATH, EPIDEMIOLOGY, FORENSIC MEDICINE

În mod obişnuit, se consideră că suicidul este un act de autoprivaţiune, conştientă, de viaţă a individului care, deseori, interferează cu accidentele şi omorurile. Aceste trei tipuri de privaţiune de viaţă a omului au simptome similare şi se raportează ca moarte violentă (1,2,3). De aceea, nu poate fi considerat suicid autoprivaţiunea de viaţă a unui individ aflat în stare de inconştienţă sau moarte care a survenit din neglijenţa victimei (4,5).

În unele situaţii, individul comite anumite acţiuni autoagresive, care demonstrează suicidul, prevăzând posibilitatea morţii, dar sperând că va rămâne în viaţă („suicid demonstrativ"). Dacă în asemenea cazuri se înregistrează sfârşitul letal, fapta va fi calificată nu ca suicid, ci ca deces din lipsă de precauţie (6,7).

Caracterul complex al unor evaluări epidemiologice şi medico-legale asupra morţii prin suicid este determinat de faptul că, deseori, familia victimei încearcă, din anumite considerente, să ascundă cauza adevărată a decesului, prezentându-l ca fiind urmarea unui accident, modificându-se, astfel, imaginea generală asupra cazului aflat în cercetare (8,9,10).

În cele ce urmează, s-a urmărit evaluarea descriptivă a factorilor incriminaţi în inducerea suicidului, la nivel naţional, comparativ cu judeţul Iaşi, cu implicaţii educa-

ţional-prevenţionale.

MATERIAL ŞI METODE

În studiu au fost incluse informaţiile acumulate la nivel naţional, prin evaluarea rapoartelor privind sinuciderile şi alte cauze ale morţii violente, realizate de Institutele de Medicină Legală, prelucrate şi interpretate prin metode epidemiologice şi biostatistice, în perioada 1997-2006.

REZULTATE ŞI DISCUŢII

1. Sinuciderile şi alte cauze ale morţii violente. Evaluarea dinamicii fenomenului suicidar, la nivel naţional şi, comparativ, în judeţul Iaşi, a evidenţiat, pentru perioada 1997-2006, valori ale incidenţei anuale ale sinuciderilor cu creşteri semnificative ($p < 0,05$) de la 18-23,4% în anii 1997-1999, la valori apropiate de 30% în ceilalţi ani (fig. 1). În afară de sinucideri, moartea violentă a fost provocată şi de alte cauze, cu diferenţe anuale nesemnificative ($p > 0,05$), cuprinse într-o medie de 70-80% din total (tab. II).

2. Evoluţia anuală a incidenţei sinuciderilor în judeţul Iaşi. În perioada 1997--2006, valorile de incidenţă a sinuciderilor de toate cauzele au înregistrat diferenţe anuale nesemnificative ($p > 0,05$). În 4 ani, acestea au fost de 1,1‰ locuitori, în alţi 4 ani, 1,2-1,3, cu valori de 1,6 în 2006 şi 2‰ în 2003 (tab. II).

În anul 2003, cu rata cea mai ridicată a sinuciderilor (2‰ loc.), analiza mecanismelor de producere a leziunilor tanato-generatoare a evidenţiat situarea, pe primul loc, a spânzurării (70%), urmată, la mare dis-

TABELUL I

Principalele cauze ale sinuciderilor evidenţiate prin autopsii medico-legale, înregistrate la nivel naţional, în perioada 1998-2006

Anul	Cauze - % din total *						
	Precipitare	Spânzurare	Intoxicații	Plăgi tăiate	Submersie	Împuşcare	Altele
1998	14	6	4	1	1	0	74
1999	10	65	14	0	8	1	2
2000	31	50	12	0	0	1	6
2001	23	52	14	0	0	2	9
2002	9	40	10	1	3	1	6
2003	9	72	8	0	4	0	7
2004	8	70	10	3	5	1	3
2005	3	77	11	2	3	1	4
2006	6	78	8	2	3	1	2

* pentru valorile mai mici de 10, proporţiile sunt orientative

TABELUL II

Evoluţia numărului de sinucideri înregistrate în judeţul Iaşi, în perioada 1997-2006

Anul	Populaţia	Cazuri	
		Nr.	‰ooo
1997	813713	90	1,1
1998	818103	94	1,2
1999	822005	93	1,1
2000	825855	92	1,1
2001	829437	94	1,1
2002	807777	105	1,3
2003	808887	147	2,0
2004	808595	107	1,3
2005	808886	107	1,3
2006	824083	130	1,6

tanţă, de precipitare (9%), intoxicaţii (8%), submersie (4%), arsuri (1%), electrocuţii (1%). În categoria "alte metode", s-au inclus 5% din cazuri (fig. 2).

3. Repartiţia pe grupuri de vârstă a sinuciderilor, în judeţul Iaşi. În perioada 1997-2006, cumulativ, la % din total, grupurile de vârstă implicate în sinucidere au prezentat diferenţe semnificative ($p < 0,05$): 41-50 ani (22,2%); 31-40 ani (19,1%); 51-60 ani (18,9%). S-a observat că intervalul demografic 31-60 ani a înregistrat 60,2% din total cazuri de sinucidere. Aceste grupuri de vârstă se caracterizează printr-o intensă inserţie socială, care le expune unor stări de stres, adesea conflictuale, cu frecvente riscuri suicidare (fig. 3).

4. Evoluţia sezonieră şi pe sex a sinuciderilor, înregistrate în judeţul Iaşi. În cei 10 ani luaţi în studiu, incidenţa, evaluată cumulativ, a sinuciderilor, a avut o dispersie multilunară, cu creşteri semnificative ($p < 0,05$) în intervalul aprilie – iulie, situaţie care poate fi explicată, cel puţin în parte, prin accentuarea sezonieră a stărilor conflictuale, sociale şi familiale, inclusiv cu implicarea consumului, în exces, a alcoolului.

Repartiţia pe sex a cazurilor de suicid, a evidenţiat o diferenţă puternic semnificativă ($p < 0,001$), cu predominanţa bărbaţilor, mai frecvent implicaţi în stări conflictuale, deseori asociate consumului excesiv de alcool.

CONCLUZII

Caracterul complex al unor evaluări epidemiologice şi medico-legale asupra morţii prin suicid este determinat şi de faptul că, deseori, familia victimei încearcă să ascundă cauza adevărată a decesului,

În perioada 1997-2006, la nivel naţional, valorile anuale ale incidenţei sinuciderilor au înregistrat creşteri semnificative, de la 18-23,4% în 1997-1999, la valori apropiate de 30% în ceilalţi ani. În 70-80% din total cazuri, moartea violentă a fost provocată de alte cauze.

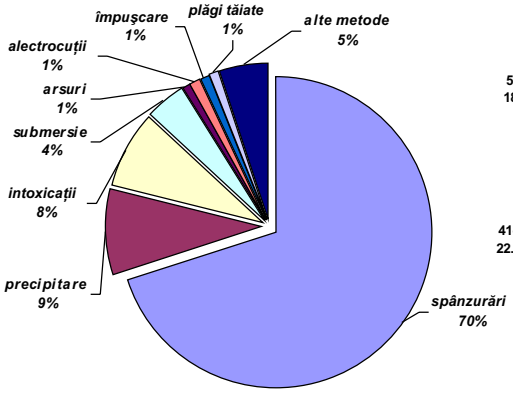

Fig. 2. Modalităţi de sinucidere, înregistrate în judeţul Iaşi, în anul 2003 (sinucideri – 2‰ooo loc.)

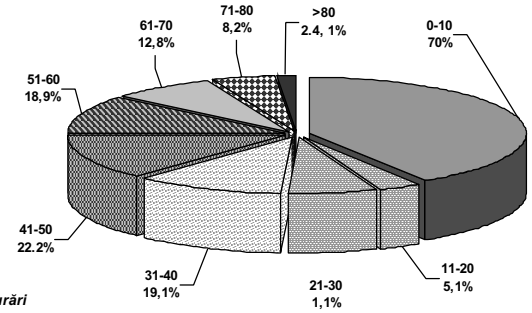

Fig. 3. Repartiţia fenomenului suicidar pe grupuri de vârstă, în judeţul Iaşi, cumulativ pentru perioada 1997-2006

În judeţul Iaşi, în aceeaşi perioadă, valorile anuale ale incidenţei sinuciderilor au variat între 1,1‰ loc, cu excepţia anului 2006 (1,6‰) şi 2003 (2‰) când, între cauzele suicidului, pe primul loc s-a situat spânzurarea.

Cele mai multe cazuri de sinucideri s-au înregistrat, în fiecare an, în lunile aprilie-iulie, cu o diferenţă puternic semnificativă, cu predominanţa bărbaţilor, mai frecvent implicaţi în stări conflictuale, deseori asociate consumului excesiv de alcool.

NOUTĂŢI

VIRULENŢA QUORUM SENSING-MEDIATĂ A TULPINILOR DE *Pseudomonas aeruginosa* CE COLONIZEAZĂ PACIENŢII CU VENTILAŢIE MECANICĂ

Pseudomonas aeruginosa colonizează frecvent pacienţii intubaţi şi este cauza pneumoniei asociată ventilaţiei (ventilator-associated pneumonia -VAP). *Köhler* şi colaboratorii au încercat să determine rolul quorum sensing (QS) ce reglează expresia factorilor de virulenţă în cursul colonizării cu tulpini de *P aeruginosa* şi dezvoltării VAP. În acest scop au fost studiate izolatele de *P aeruginosa* din aspirate traheale recoltate de la 29 de pacienţi intubaţi, dintre care 6 au dezvoltat VAP. Genotipurile şi factorii de virulenţă QS-independenţi (exoU, exoS, PAPI-1 şi PAPI-2) ale izolatelor de *P aeruginosa* ce colonizează aceşti pacienţi au fost identificate *in vitro* utilizând testele CLONDIAG. Pentru a evalua virulenţa QS-dependentă a fost măsurată producţia de elastaza şi ramnolipide. Pentru a monitoriza activitatea QS *in vivo*, ARN-ul total a fost extras direct din aspiratele traheale şi a fost măsurată expresia genelor QS. Dintre toţi factorii de virulenţă testati, numai ramnolipidele au fost asociate cu dezvoltarea VAP ($p = 0,003$), iar VAP a apărut mai frecvent la pacienţii colonizaţi cu tulpini producătoare de niveluri ridicate de ramnolipide ($p = 0,001$). Monitorizarea genelor QS *in vivo* a arătat expresia genelor ţintă la pacienţii cu VAP. În concluzie, producţia de ramnolipide QS-dependentă la izolatele de *P aeruginosa* este în legătură cu dezvoltarea pneumoniei asociată ventilaţiei mecanice (Köhler T, Guanella R, Carlet J, van Delden C. Quorum sensing-dependent virulence during *Pseudomonas aeruginosa* colonisation and pneumonia in mechanically ventilated patients. *Thorax* 2010 ; 65 (8) : 703-710).

THE IMPORTANCE OF THE MICROBIOME IN THE ALZHEIMER DISEASE PATHOLOGY-THE POSSIBLE RELEVANCE OF SOME METABOLIC DEFICIENCIES (Abstract): With the latest increased awareness on the connections that might exist between the modifications of microflora and most of the neuropsychiatric disorders, we focused our efforts from the present mini-review on discussing the possible interactions between the pathophysiology of Alzheimer's disease (the most important neuropsychiatric disorder, as judged by the number of patients affected worldwide) and microflora functioning. In addition, we speculate here about the importance of some related metabolic modifications on the context of the aforementioned importance of the microbiome in the Alzheimer's disease pathology. Keywords: MICROBIOME, ALZHEIMER'S DISEASE, METABOLISM.

Alzheimer disease (AD) is the most frequent, irremediable and gradual cause of dementia and neurodegenerative disorder among people over the age of 60, with the symptoms of the disease being described for the first time (early 19th century) by the German psychiatrist Aloysius "Alois" Alzheimer.

It can be characterized by either a late-onset (more than 95% are sporadic - sAD), but, at the same time, it can be considered a "genetic heritage" with a predisposition of appearance before the age of 60, defined by an early-onset (about 5% of them are familial - fAD).

This disease leads to a generalized damage to the brain, especially at those levels involved in cognition and behavior, by 2018 accounting for around 70% of the cases (almost 50 million people), generating gigantic costs, with a tripling of numbers expected by 2050.

Living in a microbial world, evolving in tandem with the microbiome - the total of microorganisms that populate different regions of the body, and in particular our intestines (1), lately, a growing interest has emerged in this "symbiosis", that highlights a close relationship between gut microflora and the brain.

It has been found that each individual hosts numerous communities of microbes (bacteria, viruses, fungi and archaea), this

collectivity fulfilling key functions for our health, such as biosynthesis of vitamins, provides protection against pathogen overgrowth, energy modulation and immunological, producing small bioactive molecules that mediate interactions with the host and contribute to the neurohormonal axes. Although the tendency to believe that each individual possesses the same microflora, various genetic studies indicate an inter-individual variation between the human gut microflora of each individual. For example, twins present an almost identical microbiome compared to that of siblings. However, a lot of variations are not completely elucidated, these, possibly having to do with the co-incidental colonization and stabilization of an ecosystem in a niche formed by genetics, age, biotope and nutrition (2, 3, 4).

Deregulation and dysbacteriosis of the gut microflora is correlated with a multitude of diseases in human including endocrine disorders (type 2 diabetes, obesity), dysmetabolic syndrome X, allergies, inflammatory bowel disease, colorectal cancer and Alzheimer disease (5), interactions between host and its intestinal microbiota being quite complicated, influence exerted on the adjacent organs as well as on those at a greater distance taking place through multiple pathways (6).

Current state of knowledge regarding microbiome and pathology of AD

With the completion of the human genome project in 2003, the total number of genes constituting our own DNA was estimated to about 25,000 gens. Higher pluricellular organisms represent the ideal amphitrions of a microscopic world, better known as microbiota or microbiome, forming an "super-organism", populating it from the early hours of life, total number of microbial genes being approximately 150 times higher. Compared to an individual adult whose body is estimated to be formed from about 10^{13} cells, it is currently speculated that the human microbiome is composed from about ten times more cells, ~ 10^{14} (a hundred thousand billion bacteria). Subsequently, they were grouped into three enterotypes: *Bacteroides*, *Prevotella*, and *Ruminococcus*.

Because most of them are found in the intestine, initially was thought that the gut microflora comprised between 500-1,000 species of microbes, nearly 3,500 were identified so far (7, 8). Researchers claim that they produce about 1.5 kilograms of biomass, the main genres being divided into three categories (9), containing strictly anaerobic entities, apparently, the most important role being attributed to those facultatively anaerobic such as enterobacteria and enterococci found in a rather large number in the gastrointestinal tract (GI) of neonates, their whole existence depending on the supply of dietary carbohydrates that have escaped digestion. It can be concluded that the carbohydrate mixture that enters the colon resulting from food intake, nutritional digestion, and absorption, exerts significant action upon them, creating favorable conditions for the subsequent development of those anaerobic (10).

1. *Firmicutes*, *Bacteroides*, *Escherichia coli*, *Enterobacteriaceae* and *Veillonella* - neutral;

2. *Bifidobacterium*, *Lactobacillus*, *Eubacterium*, *Fusobacterium*, *Campylobacter jejuni* - potentially beneficial;

3. *Clostridia*, *Staphylococcus*, *Proteus*, *Pseudomonas aeruginosa* -potentially harmful.

In his review, Szablewki summed up the composition and concentrations of human gut microflora in a healthy digestive tract system according to the location of the main classes of microorganisms (11).

As mentioned above, gastrointestinal tract (role in maintaining the homeostasis

and symbiosis between host and his "tenants") houses trillions of symbiotic microbes due to its interface (250-400 m^2) between the host, antigens and exogenous factors that influence normal physiology and alter the host's susceptibility to disease, essential and beneficial as well for an appropriate development of central nervous system and brain responses (12, 13, 14). Cells from the central, enteric and peripheral nervous systems form a neural network capable of sensing and responding to endo- and exogenous, as well as to the environmental ones (6), in association with hypothalamic-pituitary-adrenal axis giving birth to the so-called gut-brain axis (15).

Results of studies published over the past 10 years support the concept of bidirectional gut-brain interactions and *vice versa*, which are insufficiently understood, including metabolic, immune, endocrine and neural pathways. Central nervous system, gut and immune functions are modulated through this axis, germ free models (GF) used reflecting a role in host cognition or AD-related pathogenesis, moreover, in maintaining the integrity of the blood-brain barrier, also dependent on the microbiota and especially microbial products, short-chain fatty acids (16, 17, 18, 19).

Recent studies in which murine lines and human subjects (alive and post-mortem) have been used in the relevance of AD pathology are summarized in tab. I and II.

TABLE I

Recent studies that highlights the close relationship between AD and microbiota deregulation

Model	Procedure/Aim	Observations	Reference
Rat	intrahippocampal injection of β-amyloid	Alzheimer probiotics *Lactobacillus acidophilus-fermentum* and *Bifidobacterium lactis - longum* improves learning process, memory and ameliorates oxidative stress	(20)
Rat	injection with D-Galactose	*Lactobacillus plantarum* MTCC1325 ameliorates cognitive deficits, restored acetylcholine level and reduced amyloid plaques formation	(21)
5x fAD male mice	analysis of fecal proteins	A reduced quantity of trypsin, as well as a change of the microflora, closely related to aging.	(22)
3x transgenic AD mice	mixture of lactic acid bacteria and bifidobacteria	SLAB51 diminishes the oxidative stress in the AD mice brain by triggering the activity of a class III deacetylase histone (SIRT1)	(23)
ApoE$^{-/-}$ mice	infection with *Porphyromonas gingivalis, Treponema denticola, Tannerella forsythia* and *Fusobacterium nucleatum*	Results indicate that *Porphyromonas gingivalis* has the ability to access the ApoE$^{-/-}$ mice brain	(24)
APP/PSEN1 transgenic mice	comparative study	*Odoribacter* and *Helicobacter* genus significantly increased in APP/PSEN1 mice, and *Prevotella* genus in wild type mice	(25)
APP/PSEN1 transgenic mice	long-term broad-spectrum combinational antibiotic treatment	In APP/PSEN1 mice treated ABX, take place changes in gut microbiome as well as at circulant inflammatory mediators. Likewise, they display reduced Aβ deposition, but increased soluble Aβ, reactive gliosis surrounding the plaques being reduced	(26)

Model	Procedure/Aim	Observations	Reference
APP/PSEN1 transgenic mice	comparative study	All specimens used exhibit the same bacterial profile in the first 3 months. After 6 months, *Turicibacteriaceae* and *Rikenellaceae* increased in all groups, *Bacteroidetes* total remaining invariable. Transgenic mice were defined by an increase of *Proteobacteria* (*Sutterella*), also encountered in autism spectrum disorders cases. Furthermore, *Erysiopelotrichaceae* family was more abundant in transgenic mice, whose activity is related to inflammatory reactions.	(27)

TABLE II

Recent studies realized on human subjects (alive and post-mortem) that highlights the close relationship between gut microflora and the brain

Number of subjects	Observations	Reference
53 AD patients	AD patients infected with *Helicobacter pylori* presented a pronounced deficiency of cognitive processes	(28)
25 AD patients and 25 as control	A change in the gut microflora has been observed; a decrease in abundance of *Firmicutes* and *Bifidobacterium*, and an increase in abundance of *Bacteroidetes*	(2)
35 AD, 46 MCI and 77 as control	Of the seven oral bacteria associated with periodontitis, following testing of immunoglobulin G antibody levels, only in the case of *Fusobacterium nucleatum* and *Prevotella intermedia* levels were significantly increased in AD compared to the controls	(29)
60 participants; 30 treated with milk or a mixture and 30 as control	At the end of the twelve weeks, Mini-Mental State Examination score was considerably higher	(30)
38 elderly	An association between periodontal diseases and Aβ load was observed by using C-Pittsburgh compound B and positron-emission tomography imaging	(31)
28 individuals	Amyloid precursor protein, interleukin 1β and complement C1q subcomponent subunit A mRNA levels were considerable upregulated in periodontitis affected gingival tissues	(32)
10 AD and 10 as control	Lipopolysaccharides from periodontal bacteria can access the AD brain during life as much or even longer after the patient's death (relatively equivalent range).	(33)
25 AD, 19 MCI and 21 as control	Results revealed an increased levels of tumor necrosis factor alpha and interleukin 6 in the patients with AD/MCI and periodontitis after performing the following tests: MMSE, FAQ, periodontal and oral evaluation, blood concentrations of interleukin 1, 6 and the tumor necrosis factor alpha.	(34)
24 AD and 18 as control	The levels of *Escherichia coli* K99 and lipopolysaccharides were higher in the case of patients with AD compared with controls, lipoglycans colocalized with Aβ1-40/42 in amyloid plaques and around vessels in AD brain	(35)

Number of subjects	Observations	Reference
10 AD and 4 as control	Spirochete-specific DNA of *Borrelia burgdorferi* found in senile plaques	(36)
5 AD and 5 as control	Results indicate a characteristic presence intracellular and one non-conformal extracellular of *Chlamydia pneumoniae* antigens present in the frontal and temporal cortices of the AD brain. Furthermore, *C. pneumoniae*, amyloid plaques and neurofibrillary tangles are found in the same region of the brain there being a incongruity one to another	(37)

The relevance of metabolic and oxidative stress related deficiencies in AD-microbiome interactions

Complex pluricellular organisms, such as mammals, are provided with adequate mechanisms, ensuring the transport of oxygen to all the cells that need it (38). However, being strictly aerobic organisms can have serious repercussions on us, the reduction of molecular O_2 to H_2O during the process of cellular respiration drives both the ATP synthesis necessary to sustain life, as well as the production of free radicals (39). These reactive species, generated by nicotinamide adenine dinucleotide phosphate oxidase and nitric oxide synthase nevertheless perform important functions, such as the defense of organism against infections and activation of various signaling pathways (40).

For example, it was showed that in the patients with Alzheimer and mild cognitive impairment there is a similar decrease of the superoxide dismutase and glutathione peroxidase, concomitant with an increase of malondialdehyde level compared to the control group (41). It seems that the human brain is extremely susceptible to oxidative stress, in literature existing consistent evidence that attests that free radicals play a crucial role in triggering by reflecting the etiopathogenesis of AD (42).

Perhaps the most well-known hypothesis is the amyloid cascade who dominated the AD field over the past decades. A new one has been issued recently, more precisely the mitochondrial cascade, where dysfunctions of this organelles, combined with an increased production of reactive oxygen species, could lead to AD development (43). Du *et al.*, detailed in his review all the current hypothesis about AD known to date (44).

Although it is well known that colonization of the infant gut at birth influences normal development (45), caesarean section delivery rates have increased rapidly over the last decade (46), becoming clear the fact that caesarean section can influence in negative ways the infant gut colonization. It seems that vaginally delivered infants, compared with those by caesarean section are colonized with less beneficial microbes (*Bifidobacterium* and *Bacteroides*) and higher numbers of potentially harmful such as *Clostridium difficile*. A major impact in the early development of the new-born is assigned to breastfeeding and dietary interventions using pre- and probiotics (47, 48, 49).

The main precursors involved in the modeling and induction of intestinal microflora variations during an individual's life, which may then generate a dysbiosis, are mass industrialization and aging process, affecting the production of immune mediators and induces both chronic inflammation and metabolic dysfunction. The main contributing factors in this context are: uncontrolled drug intake, excessive hygiene, changes in diet, addictions, chronic stress, even drinking water (50, 15, 8). Nelson *et al.*, provide essential data about the genotoxic and hepatocarcinogenic effect exerted by halo acetic acids (HAA) from the drinking water upon cecal microbiota from mice.

Noteworthy is that a mutagenesis in a *Salmonella* micro suspension was observed after an incubation at different time intervals, with and without cecal microbiota (51). For example, in 2014, another group reported a possible association between alcohol consumption, cognitive functions and type 2 diabetes, after the examination of 219 patients. Their results indicate that moderate consumption can reduce some of the neuropathological aspects of type 2 diabetes, as well as a decrease of glycemic levels in patients that consume higher levels of alcohol (52). In the same year, other group confirmed a significant correlation between the serum levels of uric acid and the specific parameters of the metabolic syndrome (53).

Also, our group provided additional evidences that cardiovascular risk factors are involved in cognitive regression, results obtained after the examination of 15 patients with mild cognitive impairment and 15 with AD by mainly focusing on aspects such as body mass index importance, cholesterol levels, hypertension and their related effects (54).

It's well known that obesity and diabetes in humans are associated with increased rates of anxiety and depression, which is why Soto *et al.*, evaluated behaviors and insulin action in brain of mice with diet-induced obesity (DIO), usually characterized by a decreased insulin signaling and increased inflammation in the nucleus accumbens and amygdala. After the treatment of DIO mice with oral metronidazole or vancomycin, they observed a decreased inflammation as well as an improvement of insulin signaling in the brain (55).

Those, the aforementioned aspects we presented here could exert a fundamental importance in studying the neurobiological mechanisms of these complex neurological processes and their pathophysiological manifestations, complications and associations (56, 57, 58). By using GF rats and rats associated with human fecal bacteria, Bowey *et al.*, demonstrated that isoflavones and ligans, in particular, equal, is not produced by some subjects mainly due to a lack of specific components of the gut microflora (59).

In addition, multidisciplinary studies have revealed that various non-psychiatric systemic diseases like obesity (60, 61, 62) diabetes (63, 64, 65), cardiovascular diseases (66, 67, 68) irritable bowel syndrome (69, 70, 71) and CRC (72, 73, 74) are the result of an unstable microbial profiles.

Also, all these speculations we described in the present "metabolic" subchapter can be related to the fact that there is scarce information on this matter/no previous study on the metabolic influence on the microflora-AD interactions, according to our best of knowledge.

CONCLUSIONS

The current literature, as well as our mini report are clearly demonstrating that there are clear interactions between the pathophysiology of Alzheimer's disease and microflora functioning. In addition, we speculate here about the importance of some related metabolic modifications on the context of the aforementioned importance of the microbiome in the Alzheimer's disease pathology.

Conflict of interests

The authors have no conflict of interests to disclose, except the fact that CA is supported by a research great for Young Teams offered by UEFISCDI Romania, no. PN-III-P1-1.1-TE-2016-1210, contract no. 58 din 02/05/2018, called "Complex study regarding the interactions between oxidative stress, inflammation and neurological manifestations in the pathophysiology of irritable bowel syndrome (animal models and human patients)".

NEWS

HPV and colorectal cancer

In the last decade, several studies have suggested that HPV might have a role in colorectal carcinogenesis. Detection of HPV in colonic tissue has led to a wide range of work proposing a causal association between HPV and colorectal cancer. The presence of HPV in colon tissue remains a highly controversial topic of discussion because of inconsistencies in result reproducibility. Inactivation of the E2 gene through genomic integration promotes the expression of the E6 and E7 oncoproteins, which antagonize the function of p53 and pRB, respectively. The resulting degradation of p53 and pRB mediated by these oncoproteins facilitates viral DNA proliferation within the host and leads to neoplasia by mechanisms well described throughout the literature. In this study based on a well-characterized Hispanic population reported to have a high incidence of HPV-associated malignancies, HPV-16 was detected in 12 of the 19 HPV-positive colorectal samples (63.2%); the remaining 7 (36.8%) corresponded to other HPV genotypes (non-typed). The distributions of HPV-16 positive tumors regarding tumor location were as follows: 33.3% (4 of 12) of the samples were found in the proximal colon (cecum, ascending colon, and transverse colon), 50.0% (6 of 12) were found in the distal colon (splenic flexure, descending colon, and sigmoid colon), and 16.7% (2 of 12) were detected in the rectum. For non-HPV-16 tumors, 2 out of 7 (28.6%) were located in the distal colon and out 5 of 7 (71.43%) were found in the rectum. A high prevalence of HPV infection (42.2%) was detected in the tumor tissues analyzed. Only 1 of the 36 (2.8%) control samples was positive for a non-HPV-16 type. In conclusion, this study reported a high prevalence of HPV infection, a high prevalence of HPV-16 and integration of the HPV-16 genome in colorectal tumor tissue from Caribbean Hispanics. (Bernabe-Dones RD, Gonzalez-Pons M, Villar-Prados A, *et al*. High prevalence of human papillomavirus in colorectal cancer in Hispanics: A Case-Control Study. *Gastroenterol Res Pract* 2016; 2016:7896716).

LATE FAT EMBOLISM COMPLICATION AFTER EARLY STABILIZATION OF FEMORAL FRACTURE. CASE REPORT

LATE FAT EMBOLISM COMPLICATION AFTER EARLY STABILIZATION OF FEMORAL FRACTURE. CASE REPORT (Abstract): Fat embolism syndrome is a multiorgan disease and a fearsome complication of traumas associated with fractures or orthopedic surgeries. Most commonly it occurs after femoral fractures and its major clinical features include pulmonary dysfunction, hypoxia, mental status changes, petechial rash, fever, tachycardia, anemia and thrombocytopenia. The here presented case is a 20-year-old male patient diagnosed with a right femoral fracture following a trauma with direct impact to the thigh. The medical team recommended immediate surgical treatment, but surgery was delayed for technical reasons for 12 hours and consisted of centromedular osteosynthesis with the interlocking nail system. The peculiarity of this case is the late occurrence (5 days after trauma) of this potentially fatal complication which fortunately was diagnosed when the patient was still hospitalized thus making possible the rapid initiation of specific therapeutic measures that ensured patient survival and complete remission of symptoms, without sequels. **Keywords:** FAT EMBOLISM, REAMING, OSTEOSYNTHESIS, PULMONARY DYSFUNCTION, FRACTURE.

Fat embolism syndrome (FES) was first described by Zenker in 1861 as fat droplets in the lung capillaries of a railroad worker who sustained fatal thoracoabdominal injuries (1). Later, the femoral fracture was identified as the main cause of this potentially fatal complication with pulmonary, neurological, hematological and dermatological manifestations. Studies have established that the incidence of this syndrome ranges from 0.5% to 11% in the patients who sustained long bone fractures (2) and mortality rate is high, of about 20% (3). Differential diagnosis should be made with other acute respiratory diseases such as pulmonary embolism, ARDS, pneumonia, thoracic trauma (4). Neurological manifestations are rare but may be dramatic and loss of consciousness has been described for more than two months (5). The main therapeutic resources are represented by the rapid recognition of this complication, initiation of supportive therapy and high-pressure PEEP (6). Initially the disease was explained by the mechanical theory, namely the passage of particles resulting from injury of the adipose tissue into the venous circulation of the traumatized region. The identification of an aseptic inflammatory process in the brain and lung tissue has led to the development of the second theory, namely the biochemical

theory (7). Fat embolism is represented by the occurrence of fat in the vascular system and is different from the fat embolism syndrome (8). Gurd and Wilson have proposed three major and eight minor diagnostic criteria. Major criteria are respiratory changes (radiological included), petechial rash and neurological symptoms. Minor criteria include tachycardia, pyrexia, retinal fat or petechiae, oligoanuria, fat globules in urine, sudden drop in platelet and hemoglobin levels, elevated ESR and the presence of fat particles in the sputum. Diagnosis is made by the presence of at least one major criterion and four minor criteria (9). The here reported case is that of a male patient who had a late onset of FES, 5 days after trauma, and the surgical treatment of the femoral fracture consisted in centromedular osteosynthesis with interlocking nail, performed 12 hours after trauma.

CASE REPORT

A 20-year-old pedestrian sustained a road accident in which the direct contact with the car was at the level of the right thigh. He was immediately picked up by the ambulance service and arrived at the emergency department 30 minutes after the accident. At the time of presentation, he was conscious, hemodynamically and respiratory stable, the only complaints being related to the right thigh, without any other thoracoabdominal or neurologic symptoms. Personal and family medical history did not contain significant details, the patient being a smoker for 6 years. Biological samples collected at the time of presentation showed levels close to normal for the complete blood count (Hgb 14.8 g/L, PLT-245*10^3/μL, WBC 12.5*10^3/μL), while biochemical determinations showed moderately higher levels of muscle enzymes, explained by the significant muscle contusion. Pulmonary and pelvic X-rays showed no pathological changes, heart rate was 110, respiratory rate 24, no craniocerebral trauma was detected, and the neurological examination revealed no changes. The initial diagnosis was isolated right femoral fracture and the medical team recommended the immediate surgical stabilization with a centromedular nail. Surgery could not be performed urgently for technical reasons (lack of complete nail insertion tools) and was delayed for 12 hours, while the patient received antalgic medication.

Surgery was performed under spinal anesthesia and consisted in close reduction and fixation with a 10-mm austenitic stainless steel antegrade nail. The medullary canal was prepared with 9-12 mm reamers, which allowed the easy insertion of the implant (fig. 1).

Fig. 1. Preoperative and postoperative aspect of the right femur. Centromedular osteosynthesis with a reamed antegrade nail

Operative time was approximately 60 minutes, the patient remained stable throughout it, and the blood loss from surgical incisions was insignificant. The biological constants were checked immediately after surgery revealing a 3.4 g/dL decrease in hemoglobin level (postoperative Hgb 11.4 g/dL), explained both by the

preparation of the medullary canal and by the hemodilution induced by the intravascular infusion of intraoperatively perfused solutions. During the first three postoperative days the course was favorable both locally and in terms of general state, the patient being neurologically normal and mobilizing himself the same day of surgery, moving actively and completely the joints in the proximity and resuming walking with partial weight-bearing on the operated lower limb. Biological samples collected three days after trauma showed a Hgb level of 10.1 g/dL and still elevated creatine-kinase level (1434 U/L), while the remaining muscle enzymes tended to return to normal. The clinical picture of the patient changed suddenly on the fourth postoperative day when he first presented a temperature rise (38°C) and later the mental status deteriorated and he became confused, complaining of bilateral chest pain followed by respiratory dysfunction requiring oxygen administration. Emergency collection of biological samples revealed a significant drop in hemoglobin level compared with the previous day (from 10.1 to 6 g/dL, HCT-18.8%), which could not be explained by a prolonged bleeding at the fracture focus. For the first time after trauma, coagulation tests showed modified levels and the muscle enzymes which previously showed a tendency to return to normal were rising again. Higher levels of leukocytes, ESR, C-reactive protein and fibrinogen indicated an inflammatory syndrome of suspected septic origin with a starting point in the lungs or operated fracture. An emergency chest X-ray revealed changes in lung appearance compared to the initial one, which was normal. At the level of both pulmonary areas, the patient presented an alveolar filling syndrome in small and confluent foci, picture known in the literature as ground-glass airspace disease (fig. 2).

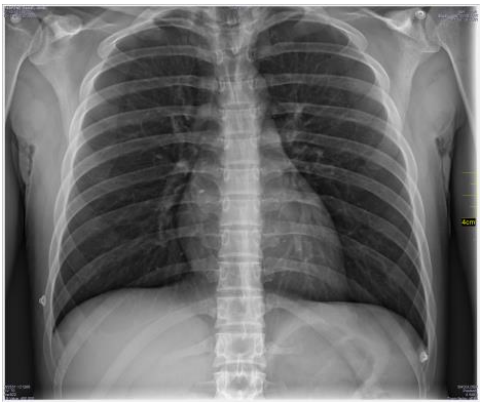

Fig. 2. Normal chest X-ray on admission

The occurrence of severe respiratory failure required patient's transfer to the intensive care unit in order to benefit from the best therapeutic measures and BiPaP respiratory support. Intravenous broad-spectrum antibiotics (Levofloxacin), corticotherapy, volemic repletion, blood transfusion, and antalgic medication were initiated. During the first 24 hours, no changes were recorded both in respiratory and neurological terms, and the biological constants were at the same level, with the exception of hemoglobin which continued to drop to a minimum of 5.8 g/dL although two units of red cell concentrate were transfused. Inflammatory markers (ESR, CRP, FBG) were still elevated while presepsin levels were within normal range throughout hospital stay. Blood cultures during the inflammatory syndrome remained negative for both aerobic and anaerobic germs, and thus the suspicion of respiratory failure due to lung infection was refuted.

The second diagnostic hypothesis was pulmonary thromboembolism, the patient not receiving on admission the usual dose of anticoagulant because it was intended that surgery to be performed as soon as possible. Due to technical problems surgery was delayed for 12 hours, the patient not being on anticoagulant protection for 24

hours from the time of the trauma. Cardiology consultations after the transfer to the ICU, supported by the ultrasound appearance of the heart and large vessels did not find clinical and laboratory elements able to explain respiratory failure as a result of pulmonary thromboembolism. The sudden drop of hemoglobin level has raised the possibility of autoimmune hemolysis due to hypersensitivity to a product administered in the hospital or the occurrence of FES. Following the hematological consultation, the administration of corticotherapy, methylprednisolone 250 mg/day, was recommended and the therapeutic effect was spectacular, with the normalization of the neurological status, the infiltrative appearance of the lungs progressively remitted, and hemoglobin level reached 9.5g/dL after 7 days of administration, when corticotherapy was stopped. The patient was discharged 14 days after trauma without neurological or pulmonary sequels and came for clinical and radiological follow-up three months postoperatively when the healing of the femoral fracture was confirmed, which made possible the resumption of pretraumatic activities.

DISCUSSION

Fat embolism is usually the complication of high energy trauma, especially in the case of pelvic and femoral fractures. Among the factors predisposing to this syndrome are younger age, the polyfractured patient, bilateral femoral fracture, closed fracture, the conservative treatment of the long bone fractures (10). There are exceptions when low energy trauma by falling from the same level and simple fracture of the femoral neck caused fat embolism syndrome (11). The main manifestation is pulmonary, which is the expression of pulmonary vascular bed obstruction by fat globules and the aggression exerted by free fatty acids on the pulmonary and brain capillary endothelium. The late occurrence of respiratory dysfunction is an argument in favor of lesions induced by biochemical mechanism. Mortality is estimated by Wildsmith to range from 5% to 15% and increases up to 36% in patients requiring mechanical ventilation (12). Prompt diagnosis is the one that offers the chance of survival and healing without sequels. Consultation and specific cardiology investigations are absolutely necessary to rule out the possibility of a cardiovascular cause of respiratory failure, chest X-ray remains the most accessible investigation that captures the characteristic infiltrate scattered throughout both lung fields, CT scan provides additional data on lung and large vessel changes and the cerebral MRI identifies the anatomical substrate of neurological manifestations. Corticotherapy is an important treatment resource and has proven its effectiveness in the case treated by us. Its prophylactic administration is not a practice that is routinely recommended and applied to patients at risk. The purpose of treatment is to support pulmonary function and to fight other complications by maintaining a level as close to normal as possible of blood gases and oxygenation, volemic repletion, parenteral nutrition, prophylaxis of deep vein thrombosis, gastrointestinal protection. McDermott recommends the administration of albumin both for its protective effect on the vascular bed as well as by its binding with free fatty acids, thus limiting their harmful effect on lung endothelium (13). Recent and older studies recommend the early stabilization of long bone fractures and especially of femoral fracture for the prophylaxis of FES (14, 15). Our case, of a patient operated relatively quickly, 12 hours after the accident, and who developed late FES, 5 days after the trauma, signals the high risk in a

young patient who sustained a high-energy femoral fracture and in which centromedular osteosynthesis with reamed femoral canal was performed.

CONCLUSIONS

Of all medical specialties, traumatology and orthopedic surgery are at the highest risk of complications by FES, which once present has a high rate of sequels and mortality. The young patients with femoral fracture, especially those with bilateral fracture, should be considered as a risk group and require careful clinical and laboratory supervision to surprise the manifestations type tachycardia, tachypnea, hypoxia, temperature rise, thrombocytopenia. Immediate fixation of long bone fractures and especially of femur fractures has been shown to reduce the incidence of this complication. High-energy trauma, 12-hour delay of surgery, young age, femoral canal reaming are causes that favored the occurrence of FES in the here reported case. In conclusion, our patient developed a less common form, particular by the late occurrence of FES, but presented its main specific manifestations. Early diagnosis, supported by the chest X-ray appearance and the rapid initiation of corticotherapy and supportive therapy made possible the complete remission of neurological and pulmonary lesions.

PREVALENCE AND ANNUAL RISK OF TUBERCULOUS INFECTION TO CHILDREN AND ADOLESCENTS IN TWO HIGH ENDEMIC TB COUNTIES FROM ROMANIA (Abstract): The prevalence of Latent Tuberculosis Infection (LTBI) and Annual Risk of Tuberculosis Infection (ARTI), key epidemiologic indicators used to estimate the transmission of tuberculosis in the community, have not been evaluated in Romania. The aim of the study is to estimate the prevalence of LTBI and ARTI in children and adolescents from two areas with increased TB endemics: Constanta and Timis. **Material and methods:** We performed an epidemiological observational study to estimate the prevalence of LTBI, using tuberculin skin test (TST), in a representative sample size of the population aged 0-16 years in both areas, regardless of the presence or absence of BCG post vaccination scarring. **Results:** 1,928 children and adolescents were evaluated, 1,088 from Constanta (CT) and 840 from Timis (TM). The LTBI prevalence for the studied group was 12.81% (CT-11.86% and TM - 14.05%), for boys 12.46% (CT-11.34% and TM-14.11%) and girls 13.21% (CT-12.53% and TM-13.98%). The prevalence of LTBI was 8.2% in the urban area (CT-9.19%, TM-7.02%) and 4.5% in the rural area (CT-2.67% TM -7.02%). ARTI for the study cohort was 1.64% (1.58% CT and 2.19% TM). In 2016, the TB global incidence (GI) in the two analyzed areas (CT = 73.7% per 100,000, and TM = 70 per 100,000) was higher than the national one (GI = 64.8 per 100,000). **Conclusions** The values of LTBI and ARTI prevalence in the two analyzed territories were comparable, but significantly higher than in other developed countries, and similar to those with high TB global incidence. **Keywords:** LATENT TUBERCULOSIS INFECTION**,** THE ANNUAL RISK OF TUBERCULOSIS INFECTION, COUNTY EPIDEMIOLOGICAL SURVEY, CHILDREN.

Tuberculosis (TB) continues to be an important public health problem in Romania (RO), with a global incidence of 64.8 per 100,000 in 2016 (1). The TB incidence in children 0-14 years was 19.4 per 100,000 (1). Although there has been a steady decrease in the TB endemic since 2002, it is necessary to remain vigilant in the control of this disease in the territory, as long as Romania has the highest amount of cases in the EU region, with an important mortality and fatality rate (2). The prevalence of latent TB infection (LTBI) is a useful tool to assess the trend of the TB endemic in one territory (3,4). Annual Risk of Tuberculosis Infection (ARTI), although

controversial in the model proposed by Styblo to predict the incidence of contagious TB cases, remains a key epidemiological indicator of appreciation acquiring TB infection during a year (5,6). Both indicators, the prevalence of LTBI and ARTI, are calculated using the tuberculin skin test (TST). Despite its simplicity, efficiency, and reliability, Romania does not routinely apply the LTBI prevalence and ARTI to assess the trend of infection and to make TB control measures more effective at a national level.

THE OBJECTIVE of our survey was to estimate the prevalence of LTBI and to estimate ARTI in the population of children and adolescents, in two areas with increased endemics in Romania (Constanta – CT, and Timis - TM).

MATERIALS AND METHODS

Study cohorts

We conducted a cross sectional survey to estimate the prevalence of LTBI in two counties with high TB incidence from Romania: CT and TM. The sample was randomly selected from preschool and school college children living in the two counties. We excluded from the study those who showed signs of fever, cutaneous atopy, childhood eruptive diseases, immunosuppressive illness, malnutrition, active TB, or other vaccination done a month before TST, and those whose parents or tutor refused to sign the informed consent. The size of BCG scar was not an exclusion criterion. 1,088 children from CT and 840 children from TM, aged 0-16 years, who are attending school, have been tested using TST. For the two cohorts of participants, the basic demographic characteristics were collected. The clinical exam for all participants was performed by the pulmonologist. The Mantoux test was performed using 5 UT tuberculin units (TU) of PPD RT23 provided by the Statens Serum Institut, Copenhagen, Denmark, according to the standard protocol (7,8). The correctness of the technique was followed by the occurrence of a pale skin papule of 5-6 mm. The induration was measured 72 hours later (8). The TST was considered positive if the transverse diameter of the induction was equal to or greater than 10 mm. We calculated the prevalence of LTBI using cut-off points of 10 mm (positive TST), as it is widely accepted for the diagnosis of LTBI in the conditions of vaccination of over 95% of the Romanian population. To avoid errors on the validity and reproducibility of the test, the same team of doctors and nurses participated in the whole study.

Statistical analysis

The experimental data was processed using the statistical processing program IBM *SPSS Statistics v.20.0* software *(SPSS Inc., Chicago, IL, USA)*. We have been used descriptive statistics (to characterize discrete and continuous variables defined at the database level), and nonparametric statistical tests (chi-squared test for the comparison of two proportions). The continuous variables were presented as means and standard deviations, and the categorical variables were presented as frequencies and percentages. Chi-square test was used to compare the prevalence of LTBI in the two geographical areas in relation with different variables: age, sex, and home environment (8, 9). P-value <0.05 was considered significant (9).

Measurements

Prevalence of LTBI - was calculated by reference to the number of positive TST in 100 subjects (children and adolescents)

tested, according to the formula below (10, 11):

$$P=\frac{\text{Number of children with positive TST x 100}}{\text{Total number of children analyzed}}$$

Estimation of ARTI - The standard formula used to estimate the probability of being infected in one year (ARTI) was: $R = 1-(1-p)^{1/age+0,5}$ **(**where R is the annual risk of infection, P represents the prevalence of LTBI, and age indicates the average age of children and adolescents studied) (5,9). For a percentage estimation of ARTI, the result of the standard formula was multiplied by 100 (8).

Population

According to the ARTI protocol, the estimation of the sample size survey was made by using the formula: N=d (1.96)2 (1-P)/ε2P (8), where **N** is sample size, **d** represents the design effect (the value after protocol is 3), **P** is the expected prevalence of LTBI, ε is the relative precision which reflects the error degree between the estimated prevalence chosen at the beginning of the study, and the real prevalence of LTBI after the study (15%) (10, 11). Due to the lack of other epidemiologic studies in Romania regarding the prevalence of LTBI in children and the fact that the incidence of contagious forms of TB is high, we chose a hypothetical prevalence of 20%. According to these calculations, the estimated population for our study was 2,148, and finally, the group studied included 1,928 children and adolescents.

Ethics statement. Written informed consent for tuberculin testing was obtained from the parent or tutor of every child. The Ethics Committees of the Clinical Pneumology Hospital Constanta and Clinical Hospital of Infectious Diseases and Pneumology "Dr. Victor Babes" Timisoara approved the study protocol.

RESULTS:

Study setting and population characteristics

The study was conducted in two high endemic TB counties, geographically located in opposite areas of Romania: CT and TM. TB global incidence (GI) in these areas was always above the national values. Since 2002, the evolution of the TB endemic in both counties has followed the same decreasing tendency as at the national level. The global incidence values over the last four years are shown in Table I.

This study was conducted during 2014-2015. 1,928 children and adolescents aged between 0–16 years participated in this survey: 1,088 from CT and 840 from TM, irrespective of their BCG scar status. In our country, the BCG vaccination is given at birth or as early as possible within the first month of life, and national BCG vaccine coverage has been >95%.

The baseline participants' characteristics and LTBI calculation by population categories are presented in Table II.

The average age was higher in TM county, 8.84 years compared to CT, 7.9 years ($p<0.001$). The TM subjects included a greater proportion of adolescents aged 15-16 years (14.6% TM vs. 5.5% ($p<0.001$). The LTBI prevalence for the study group was 12.81%. The proportion of subjects with a positive TST test was 11.86% in CT and 14.05% in TM ($p=0.153$). There was a significantly higher proportion of absence in CT of 10.85% compared to TM-3.93% ($p<0.001< \alpha = 0.05$). In the studied group, the LTBI prevalence was 6.69% in boys (CT-6.43% and TM-7.02%), and 6.12 in girls (CT-5.42% and TM -7.02 %) showed in table II. LTBI prevalence values by age

group compared in the counties are shown in Figure 1 and Table III.

The highest value of LTBI prevalence was recorded at the age of 2 years in CT (2.85%) and the age of 14 in TM (1.67%) (table III). There are significant differences between the TST positive score recorded in CT (2.85%) and TM (0.71%) for the age of 2 years ($p<0.001$).

BCG vaccination could influence a high prevalence of LTBI in CT at 2 years of age, in an urban area; the differential diagnosis of LTBI and post-vaccinal positive TST reaction could be made by the T-SPOT-TB assay which is more specific for the positive diagnosis of LTBI than the TST (12). In CT the prevalence of LTBI was higher in the urban area (9.19%) *versus* rural area (2,67%). Compared to CT, in TM there were no differences between environmental field and sex. The evaluation of the induration diameter revealed a percentage of 8.07% of subjects with a TST diameter of > 15 mm, suggesting either a recent TB infection requiring further investigations to

exclude an active disease, or a person at risk for the transformation of a latent infection into the disease, requiring careful monitoring. ARTI on the cohort studied was 1.64%. ARTI was 1.58% in CT and respectively, 2.19% in TM, given that in 2016 the global incidence in the two analyzed areas was 73.7% in CT and 70% in TM respectively. As $\chi^2_{calc} = 2.13 < \chi^2_{cr} = 7.81$, respectively $p = 0.547 > \alpha = 0.05$, it is considered that there are no significant differences in percentage of ARTI values registered by age groups in the two counties. The ARTI was 0,42% in CT and 0.50% in TM for 5-9 age group. For both counties ARTI decreases with age.

DISCUSSION

Until now, no LTBI or ARTI prevalence studies have been conducted in Romania. In our country, TST is currently used in epidemiological investigations for LTBI detection in TB outbreaks or for primary TB symptoms in children. According to the National Guidelines, a TST ≥ 10mm response is considered positive, meaning a natural infection with *Mycobacterium tuberculosis;* whereas, a TST over 15 mm is considered an intense reaction, with the probability of an increased risk of lesion evolution. Our study was the first large survey to estimate the prevalence of LTBI and ARTI in Romania. LTBI prevalence was 12.8% in the study cohort. The ARTI value was 1.58% in CT and 2.19% in TM and was highest in the 1-4 years age group. The study was conducted in two regions with a high tuberculosis endemic, but with some socio-economic and cultural particularities.

CT is located in the SE of Romania, influenced by the sea climate, and the harbor on the Black Sea. In 2014 CT had an incidence of TB of 87.6 per 100,000. As a harbor, which by itself brings heterogeneous and migrant population, we considered that besides commonly known TB risk factor such as malnutrition, smoking (including electronic cigarette vaping in adolescents), TB-HIV coinfection, and low socio-economic status (13-15), there are other specific local conditions that can influence the level of LTBI in Constanta, such as the emigration phenomena, or institutionalization in care homes and prisons (16,17). Environmental and occupational exposure due to a petroleum refinery in the area could also compromise the systemic immune response and increase the risk for LTBI as well as lung cancer (18,19).

TM, situated in the western region of Romania, with Western influences, is known for a higher living standard, where TB incidence was 85.2% per 100,000 in 2014 (Table 1) (1).

ARTI results in our study on incidence confirms the Styblo coefficient - each 1% ARTI corresponds to an incidence of 50 per 100,000 inhabitants (6). The estimated values of TB incidence after Styblo rule (79 %000 inhabitants in CT and 109,5 %000 in TM) are close to the real ones.

Although the ARTI is the simplest and the most effective and reliable indicator to estimate the epidemiological situation of TB, many developing countries do not use ARTI. For instance in Saudi Arabia, two studies were published: one by Al Kassimi in 1993 where the prevalence of LTBI was 5.6%, and ARTI was 0.5 % for the 5-8 year group, and another by Balkhy, published in 2017, where the LTBI in the population under 15 years old was 2.9% (3.6% in girls and 1.5% in boys) (20,21). In Saudi Arabia the global incidence of

TB was 50% per 100,000 in 1990, and 12% per 100,000 in 2014 (22). A nationwide cross-sectional study of primary school children aged 6–11 years conducted in 2011 in Gambia revealed a prevalence of LTBI using a 10 mm cut-off point of 10.8% in girls and 12.3% in male, and an ARTI of 1.27% (23). Another survey from 2004 performed in the south of India on children aged between 1-9 years, without a BCG scar, found a prevalence of LTBI of 5.9%, and a corresponding ARTI of 1.0% (24). In Europe, there are very few studies on the prevalence of LTBI and ARTI, and these are targeted at at-risk populations such as health workers, HIV-infected individuals, patients treated with anti-tumor necrosis factor agents, and foreign-born people from countries where TB is endemic. The study of Gallegos Morales found an LTBI rate in foreign-born students in Lübeck Germany of around 10% (25). However, a comparison and interpretation is difficult to produce, due to the notable differences in the methodology of the TST survey: different population groups studied, different immunosuppressed condition (26), severe disseminated forms of TB (27), associated comorbidities (28), different tuberculin concentrations (1 TU, 2 TU, 5 TU PPD), different cut-offs for TST test, the presence of BCG vaccination or the use of IGRAs in TST place for LTBI confirmation (11,23).

A limitation of this study could be the small size of the cohort analyzed on different age groups. Another limitation of the survey is that the studied population included age groups 10-16 years old in a BCG vaccinated population. The ARTI protocol suggests that it is preferable to conduct a survey on children under 10 years old (8). It is also possible that the small number of non-vaccinated BCG children introduced in the study could influence the results (29). For a better evaluation of LTBI, Interferon Releasing Assays (IGRAs) are recommended because TST has several limitations (12), but both of them are inconsistent with active TB diagnosis (30,31). However, the both tests do not confirm the diagnosis of active TB, but in same circumstances could be a suggestive tool to doubt TB etiology of disease (32,33).

The age group that appears to be the most affected by BCG vaccination and interferes with the results of the study is age group 0-4 years, as it seems to have happened in CT. Between 5 - 9 years old, LTBI prevalence is relatively stationary and comparable in the two counties: 0.42% in CT and 0.50% in TM. Considering the gender difference regarding transmission of LTBI, we should to be aware of the young women with childbirth potential who need to be included in the TB annual screening when the above-mentioned risk factors are present (34). Education has proven to be instrumental in promoting a healthy and smoke free behavior in the younger population (35). In the same time, it has become critical to control smoking as a public and personal responsibility, not only for the smoking cessation but also for the prevention of COPD (36). Therefore, education in the prevention of the contagious infectious disease, such as tuberculosis, remains the most important method to decrease the prevalence of one of the most frequent disease in Romania.

We believe that the strength of the study consisted of the fact that it was carried out in two counties with similar endemics and the results on LTBI prevalence

and ARTI were not significantly different.

CONCLUSIONS

The high risk of TB infection estimated in our study (1.58% CT and 2.19% TM) indicates that it is necessary to provide sustained and committed quality services for tuberculosis control at national level with a periodic repetition of prevalence surveys. Case detection should be improved by maintaining DOT and quality of care.

This study provided all the necessary data to assess the impact of the disease and to evaluate future national epidemiological trends.

Acknowledgment: To the Constanta and Timis pneumology medical team members for their great work.

AGGRESSIVE ANGIOMYXOMA OF THE VULVA IN POSTMENOPAUSAL PERIOD: LITERATURE REVIEW AND CASE REPORT (Abstract): Aggressive angiomyxoma (AA) is a rare, benign and slowly growing mesenchymal tumor which affect women especially on the reproductive age. Because over 80% of cases are misdiagnosed and most of them are often confused with lipomas, the diagnosis is made by histological examination. We describe here a case of an 89-year-old female, at menopause, that presented with a large pedunculated angiomyxoma on the right upper of major labia. The vulvar AA diagnosed was made due to clinical-pathologic findings and histologic result after the local excision of the tumor. The patient was discharge 7 days after surgery and along of 7 months of follow-up no recurrence or metastasis were documented. In this case we showed the diagnosis, management and prediction for vulvar angiomyxoma in postmenopausal period, but further follow-up period is necessary for surveilling the recurrence, knowing that the tumor it may reappear in between 2 months and 12 years. **Keywords**: VULVAR AGGRESIVE ANGIOMYXOMA, VULVAR BENIGN TUMOR, VULVAR LIPOMA.

Steeper and Rosai, firstly described an aggressive angiomyxoma (AA) in 1983 and, at the moment, there have been reported in the literature around 300 cases of this tumor type (1, 2). Aggressive angiomyxoma of the vulva is a benign, invasive myxoid tumor that primarily occurs in the pelvic, perineal and genital region. This tumor affects especially adult women in their reproductive age, having a women-men ratio of 6.6 : 1. When occurs in men, usually is being spread in different places like scrotum, perineum, spermatic cord, testicular/spermatic cord neoplasm, spermatocele and hydrocele (3, 4).

Its development is mainly from the connective tissue, having a fibroblastic or myofibroblast origin. Mostly, AA appears in premenopausal women, and resembles with another similar lesions from this areas like Gartner's duct cyst, Bartholin's gland cyst, inguinal hernia, lipoma and leiomyoma (2). Even if it is a benign tumor, in the literature has been reported an increased rate of local recurrences and invasion, around 30% to 72%; metastases cases and even death

(3). The pathophysiology of the tumor remains unclear and the diagnosis has to be certified by histological examination, due to its large number of misdiagnose, more than 80% (5).

After analyzing the tumor cell biology, the researchers had reached the conclusion that suppressive hormonal therapy with estrogen and progesterone plays a crucial role in the pathogenesis of AA, due to its favorable clinical response after treatment with GnRH analogues, estrogen/progesterone receptor blockers and aromatase inhibitors (6). In this pathology, another treatment possibilities with successful results are represented by radiotherapy and angiographic embolization (7).

CASE REPORT

We report the case of an 89-year-old female with vulvar aggressive angiomyxoma who entered on the menopause since she was 45 years old and had no significant pathological conditions at the moment of the examination. She presented in our department accusing the arising of a slow growing mass that started two years ago. The patient did not accuse any pain and had no other complains about it, except the unpleasant appearance. The clinical examination revealed a tumor mass that measured approximately 18 cm and developed from the 1/3 upper level of the right labia with a pedicle that has a length of 4 cm (fig. 1). The tumor was soft, had a gelatinous consistency and its pedicle root did not infiltrate the vaginal wall; on gynecological examination, the vaginal and cervical mucosae were normal. No associated lymphadenopathy were found. The patient' laboratory investigations were found within normal limits including complete blood count (CBC), liver and renal function tests, serum ionogram test and Ca-125 marker (10.8U/mL).

During the vaginal ultrasound examination in the left parameter, on ovarian topography, a circle nonhomogeneous isoechogenic image was detected, with a hyperechogenic aria of 76/47 mm diameter; color Doppler imaging showed random and irregular dispersed blood vessels toward the center of ovarian tumor.

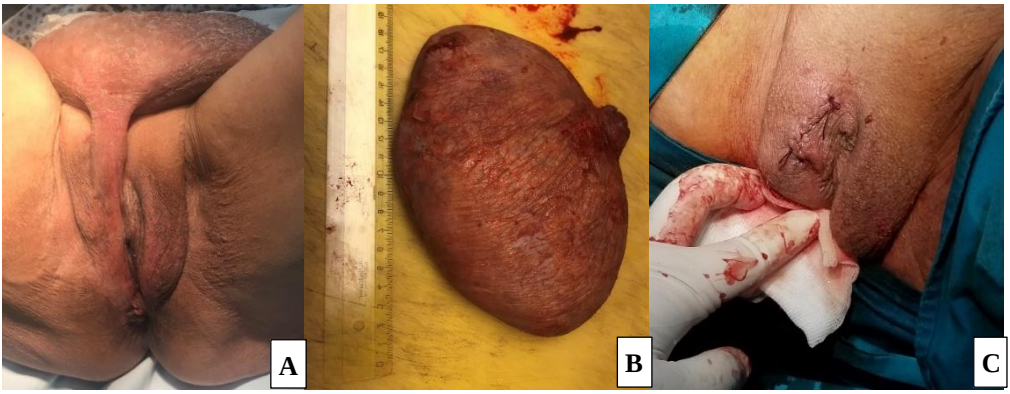

Fig. 1. A- Gross vulvar mass which developed from the right labia.
B - Image with the tumor after surgical resection.
C - Image after surgical excision of the lesion in immediate postoperative period.

The patient refused the surgical treatment for the ovarian tumor. She only consented the surgical treatment for labial tumor. This it was performed with section of the tumor pedicle (4 cm length) that was localized on the right major labia; the excision of the lesion was made with a clear resection margin. The tumor resected was sent for histological extemporaneous exploration (fig. 2). A fine local hemostasis was obtain and the lesion was closed performing an intradermal suture with Vicryl® suture (polyglactin 910). The results of extemporaneous examination of the tumor objectified a labial lipoma with the reserved result of paraffin processing of the tissue.

The patient postsurgical evolution was favorable under Ciprinol 200 mg, two tablets per day, and analgesia treatment. She left after 7 days of hospitalization. The histological examination of the tumor mass certified the vulvar angiomyxoma diagnose.

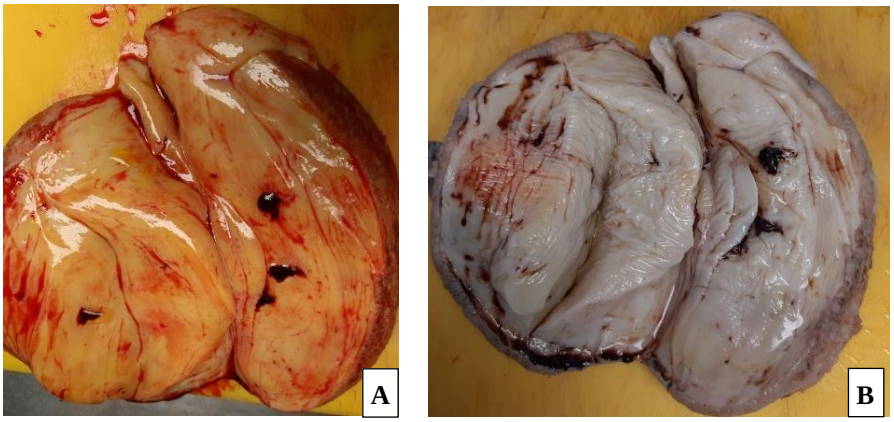

Fig. 2. Images of post operatory dissection of the labial tumor

Macroscopic histopathological examination revealed the presence of an 18/13 cm diameter tumor mass, covered by skin with ulcerated areas; the growth mass included a 3 cm thick pedicle without any visible tumor infiltration. The surface sections were gray-white with a gelatinous and glistening appearance and congestion areas.

Microscopy presented paucicellular proliferation of cells with oval or fusiform nuclei, a difficult visible cytoplasm and lack of nuclear pleomorphism or atypical mitoses. The tumor mass had relatively well delimited margins and contained abundant myxoid stroma, collagen bands and numerous blood vessels of different diameters with thin walls that were observed in hematoxylin and eosin (HE) staining (fig. 3). No hemorrhagic or necrotic areas were found. The pedicle and the excision margins found no signs of tumor infiltration.

The histopathological diagnose revealed an aggressive angiomyxoma of the major right labia. The patient had been followed during 7 months after the surgery and no recurrence or metastasis signs were remarked.

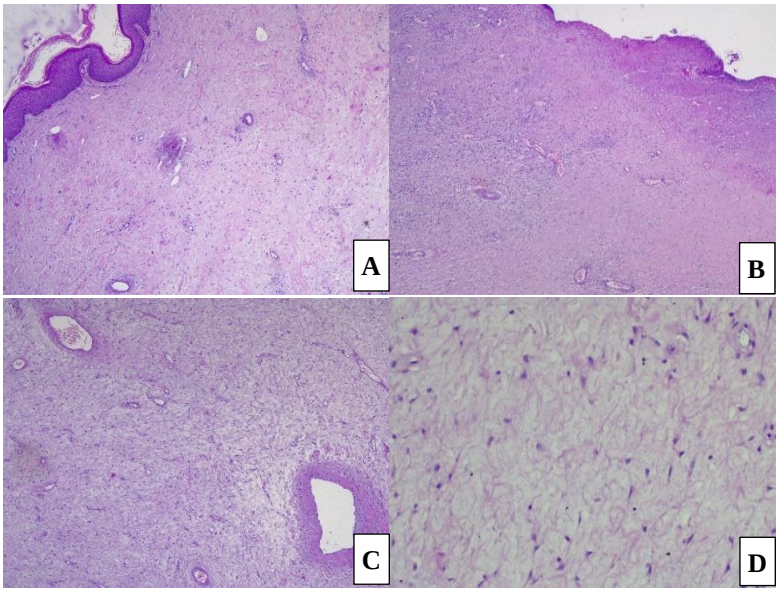

Fig. 3. The histologic aspects of aggressive angiomyxoma. **A** – Surface squamous epithelium (HE x4); **B** – Ulcerated surface epithelium (HEx4); **C** – Dilated blood vessels with different diameters and thick walls, myxoid stroma (HE x4); **D** - Myxoid stroma and fusiform cells without atypia (HEx10).

DISCUSSION

The vulvar aggressive angiomyxoma is threatening due to its characteristic of regional infiltration and recurrence (8). Nine cases were firstly reported in the literature by Stepeer and Rosai, who described different mesenchymal tumors located in the pelvis or perineum of youth females (9). Even if the number of cases increased over the years, and at this moment are counted approximately 300 cases, there are few cases reported in postmenopausal period (10, 11).

The pathogenesis of AAM is still unclear, it is believed that AAM develops from dysfunctional mesenchymal cells with genetic defects. There had been commonly found some chromosomal abnormalities that determine a translocation in the region of 12q 14-15 (12).

There are two clinico-histopathological entities: superficial angiomyxoma (SAM) and aggressive angiomyxoma (AAM). Both of them are diagnosed by the pathologist. The first category has a decreased rate of local recurrence compared with AAM, which can rise from 30% to 72%, causing the necessity of long-term monitoring (13, 14). Even if AAM has me*et al*so a favorable prognostic, two reported cases in the literature encountered a poor evolution which converted into cancer (15). The average of recurrence is one time for AAM (14).

In cases where AAM is suspected is necessary to perform preoperative imaging in order to establish the extension of the surgical excision. Computed tomography (CT) scan and Magnetic resonance imaging (MRI) offer a good predictability to what regard the tumor`s extent, both being superior to physical examination (12).

Superficial angiomyxomas are normally negative for IHC markers, except for vimentin and CD34, whilst AAMs are estrogen receptor (ER) negative and/or progesterone receptor (PR)-positive. This situation explains why clinical response is that good after treatment with GnRH analogues, estrogen/progesterone receptor blockers and aromatase inhibitors.

The "gold" standard cure is represented by radical excision of the tumor with negative margins, offering the optimum outcomes and evolution of the treatment. Aggressive angiomyxoma had shown variable responses to several adjuvant therapies such as hormonal blockade, radiotherapy and angioembolization. Hormonal therapy with GnRH agonists (leuprolide acetate or goserelin) are valuable in decreasing the tumor size in situations where surgical excision is not manageable. Radiotherapy and chemotherapy do not provide any benefits due to the tumor`s decreased mitotic activity (16). Adjuvant therapy, using arterial embolization it may be needed in cases with partial excision of the tumor mass (17).

CONCLUSIONS

The outcomes of the vulvar aggressive angiomyxoma strategies have not been properly evaluated because of the limited amount of cases for study, and evidence relies on small series and case reports. In this situation, AAM is a topically benign but aggressive mesenchymal tumor in which the surgical excision is the optimal treatment with no recurrence sign during 7 months of follow-up.

NEWS

THE INTERPLAY BETWEEN VAGINAL MICROBIOTA AND INTRAUTERINE ADHESION USING NEXT GENERATION SEQUENCING METHODS

Intrauterine adhesion represent a disease that is a very common cause for female infertility. Since it has an increased recurrence rate after surgical interventions, its pathogenesis and recurrence causes are important to understand better this condition. Liu *et al*. (2019) analysed, using high-throughput sequencing method, the vaginal microbiota of females diagnosed with intrauterine adhesion and healthy patients` vaginal secretion. The results shown that intrauterine adhesion does not bring any important changes for vaginal microbiota, having a slighty effect on the number of vaginal bacterial species. The patients with intrauterine adhesion presented at the phylum level a reduced percentage of Firmicutes and increased percentage of Actinobacteria whereas in the healthy females group the rate was more lower ($P<0.05$). Moreover, in about half of the intrauterine adhesion vaginal samples was identified at the genus level a remarkable decreased number of Lactobacillus and enhanced growth of Prevotella and Gardnerella ($P<0.05$).The interplay between synechiae and vaginal microflora can reveal remarkable changes in the vaginal microbiota diversity in patients with intrauterine adhesion. The increase of Lactobacillus population may bring interesting benefits in the endometrial regeneration process but also may help to decrease de recurrence rate of intrauterine adhesion (Liu Z, Kong Y, Gao Y, *et al*. Revealing the interaction between intrauterine adhesion and vaginal microbiota using high-throughput sequencing. *Mol Med Rep* 2019; 19(5): 4167-4174).

EXTENDED NECROTIZING FASCIITIS LOCALIZED AT THE LEVEL OF THE PERINEUM, BUTTOCK AND THE LOWER LIMB. CASE REPORT

EXTENDED NECROTIZING FASCIITIS LOCALIZED AT THE LEVEL OF THE PERINEUM, BUTTOCK AND THE LOWER LIMB. CASE REPORT (Abstract): Necrotizing fasciitis, as the name suggests, is a rare, but potentially lethal infection, with a rapidly progressive character, of the deep or superficial fasciae of skeletal muscles. In the current paper, we aim at highlighting the importance of diabetes mellitus, particularly of undiagnosed diabetes, as well as the delayed presentation to the doctor, as important risk factors for the occurrence of necrotizing fasciitis and the rapid evolution of the infection. To this respect we exemplified through the case of a diabetic patient (unknown by the time of admission) who developed an extremely severe form of necrotizing fasciitis (actually, a necrotizing fasciomyositis), extended to several areas of the body (perineum, buttock, lower limb). **Keywords:** DIABETES MELLITUS, FASCIITIS, NECROSIS, INFECTION, MORTALITY, SURGERY.

Necrotizing fasciitis, as the name suggests, represents a rare, but possibly lethal infection, with a rapid progression, of the deep or superficial fasciae of skeletal muscles, more frequently at the level of the lower limbs, perineum and trunk walls, with interest in the subcutaneous adipose tissue as well and possible (secondary) integumentary damage in the course of evolution (1, 2).

The infection and the edema produced in the muscular fascia and then in the subcutaneous tissue lead to ischemia and the necrosis of the tissues affected due to compression at the level of the vessels in that region (3). The lack of firm and rapid surgical interventions, despite the administration of the antibiotic treatment makes mortality even higher and it reaches 90% because of the occurrence of the systemic inflammatory response syndrome (SIRS) which can lead to death through its evolution to sepsis and other septic complications (4).

CASE REPORT

We present the case of a 53-year-old male urgently hospitalized with fever, chills and the presence of a bulky tumor mass (10/7 cm), fluctuance in the right ischiorectal fossa that associates local inflammatory signs, suffering which had begun 7 days before. Biologically on admission: significant leukocytosis (22,000 / mm^3), blood glucose level 510 mg/dL (unknown as a diabetic patient), serum sodium 133 mmol, urea 142 mg/dL, total lipids 478 mg/dL, C-reactive protein 20 mg/dL, fibrinogen >1,000 mg/dL. The diagnosis of right ischiorectal phlegmon was made and emergency surgery was performed by making an incision, by pus evacuation, debridement and the excision of dead tissue. At approximately 15 hours postoperatively, the patient begins to experience intense pain in the right lower limb, posterior perineum and right buttock, and the clinical examinations of those areas reveals erythema, swelling of the skin, crackling sensation on palpation and local heat. The scrotal skin and the external genitalia were not affected by the suppurative process. The tentative diagnosis of extended necrotizing fasciitis was made, localized in the posterior perineum (hence a Fournier gangrene), of the buttock and the right lower limb, with a starting point of the suppuration in the ischiorectal fossa.

Emergency surgery was performed by making wide and multiple incisions in the posterior perineal region, in the buttock and right lower limb, finding significant necrosis in the large gluteal muscle as well as in the muscle mass of the thigh and calf, liquefaction necrosis in the fasciae and subcutaneous adipose tissue (necrotizing fasciomyositis) (figs. 1, 2).

In the following days, there were also multiple areas of skin necrosis in the affected areas. The devitalized skin together with the compromised subcutaneous tissue and the muscular tissue and the necrotic tissue were excised to healthy tissue in serial surgical sessions by a team of plastic surgeons. The daily cleaning of the wounds was performed, the completion of the excisions of necrotic tissue was performed under intravenous general anesthesia, with dressings with serum and betadine. The germs identified in the wounds were *E. coli* (pus from ischiorectal phlegmon), but 2 other multidrug-resistant germs were identified, *Kluyvera ascorbata* and *Acinetobacter baumannii* (identified in the pus collected from the level of the areas with necrotizing fasciomyositis).

Fig.1. Intraoperative appearances

Fig. 2. Intraoperative appearances

In parallel, sustained treatment of hydro electrolytic rebalancing was administered, parenteral nutrition (patient on food fasting for the sterilization of the perineal region), antalgic treatment, antidiabetic anti-inflammatory (insulin with dose adjustment depending on the blood glucose level) and initial empirical broad spectrum antibiotic therapy, and then, according to the antibiogram, the patient being monitored in the intensive care unit. After obtaining granular wounds, the covering of multiple excisional skin defects was performed through several plastic surgery interventions with free split skin (fig. 3). The evolution was favorable, with small residual granular wounds, treated conservatively (fig. 4).

Fig. 3. Skin plasty - early postoperative appearance

Fig. 4. Skin plasty - postoperative appearance

Whenever possible, the active and passive monitoring of the patient was performed, and an adequate recovery treatment adapted to the patient's clinical state was performed. The patient was discharged after he had cured (fig. 5), with laboratory tests within normal limits (blood glucose level 110 mg/dL under insulin treatment), being referred to a nutrition and metabolic disease facility in order to determine the therapeutic scheme for diabetes mellitus. The control performed after 6 months shows a patient with a good general condition and healed wounds that has a normal mobility. (fig. 6)

Fig. 5. The appearance of postoperative wounds at the discharge of the patient

Fig. 6. Scarred wounds at 6 months after surgery

DISCUSSION

Diabetes mellitus predisposes to increased mortality compared to the general population (the low immune reactivity of the body of diabetic patients being known) and the necrosis of the affected necrotic tissues being more common and severe in these patients than in the general population (5), (6), (7),(8). The diagnosis of necrotizing fasciitis is made after the clinical examination, but the diagnosis of certainty is made intraoperatively through the identification of necrosis in the muscle fascia in the affected area.

In 2004, Wong and his team imagined a scoring system for the assessment of the risk of developing necrotizing fasciitis. It is called The Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) (tab. I). A score higher or equal to 6 is equivalent to a significant risk that the patient may develop necrotizing fasciitis (9), (10).

TABLE I

The Laboratory Risk Indicator for Necrotizing Fasciitis (10)

PARAMETER	RANGE	SCORE	PARAMETER	RANGE	SCORE
Hb (g/dL)	>13.5	0	Sodium (mmol/L)	<135	2
	11–13.5	1	Creatinine (μmol/L)	>141	2
	<11	2	Glucose (mmol/L)	>10	1
White cells (10^9/L)	<15	0	C-reactive protein (mg/dL)	>15	4
	15-25	1			
	>25	2			

In our patient's case, the LRINEC score on admission was 7, so there is a significant risk for him to develop necrotizing fasciitis, even though at the local examination he presents signs of inflammation only at the level of the right ischiorectal fossa.

All the studies performed in the last 30 years have concluded that the rapid and correct establishment of the diagnosis and the firm emergency surgical intervention with debridement and excision of the affected structures to healthy tissue and abundant lavage with antiseptic solutions combined with broad spectrum antibiotic therapy (empirical at first, and then adapted to the antibiogram), hydroelectrolitic and vasopressor support whenever needed (the patients being often unstable from a hemodynamic point of view) and adequate nutrition (preferably the patient be treated in an intensive care unit) are absolutely necessary measures for the attempt of saving these patients (11, 12).

CONCLUSIONS

Necrotizing fasciitis is an extremely severe affliction with a high mortality and only the prompt establishment of an adequate surgical treatment, in parallel with other measures of supported rebalancing of the patient and specific antibiotic treatment for a long time, treatment established by a multidisciplinary team (general surgeon, plastic surgeon, anesthesia and intensive care physician, recovery physician) can significantly reduce the risk of death.

Diabetes mellitus is a significant risk factor for the occurrence of necrotizing fasciitis and if we talk about an undiagnosed and implicitly untreated case of diabetes, it can significantly influence the prognosis of the patients due to the extent and severity of the lesions.

CHARACTERISTIC FEATURES OF URINARY TRACT INFECTION IN MALNOURISHED CHILDREN (Abstract): The aim of this study is to prove a relationship between urinary tract infection and malnutrition in children 0-3 years old, hospitalized in the IVth Pediatric Clinic, Hospital *St. Mary* Iaşi, between January 2000 and December 2004. **Material and methods**: We have made a retrospective study for 298 infant and young children with urinary tract infection, 237 eutrophic and 61 malnourished. We studied comparatively the both groups with urinary tract infection (UTI), and we applied statistic methods for results. **Results**: The statistic methods prove that relative risk for UTI increases in malnutrition, predictive positive value is 72.5%. The clinical manifestation is similar in malnourished and eutrophic, but many co morbidities were associated with dystrophic status. Malformation of urinary tract was associate two times more in malnourished child. The etiology of infection was dominated by *Escherichia coli, Proteus* and *Klebsiella pneumoniae*. In malnourished children 5% of UTI was determinate by opportunist etiological agents like: *Enterobacter, Enterococcus, Acinetobacter*. More frequently, bacterium develops resistance of antibiotics like aminopenicilina, Trimethoprim and Cephalosporin. **Conclusion**: Accurate and fast diagnosis and treatment of UTI in infant and child with malnutrition is the best way for nutritional rehabilitation and prevention of serious consequence. **Key words**: URINARY TRACT INFECTION, MALNUTRITION, PRETERM INFANT, EUTROPHIC, DYSTROPHIC

COMPLICATIONS IN ANTICOAGULATION THERAPY FOR PREGNANT WOMEN WITH MECHANICAL HEART VALVE. CASE REPORT AND REVIEW OF THE LITERATURE

COMPLICATIONS IN ANTICOAGULATION THERAPY FOR PREGNANT WOMEN WITH MECHANICAL HEART VALVE. CASE REPORT AND REVIEW OF THE LITERATURE (Abstract): **Aim:** Bleeding complications happen more frequently in pregnant females who carry mechanical heart valves (MHVs) compared with biological prosthesis valves (BPVs). The main objective for these patients represents a rigorous and individual monitoring of the anticoagulant treatment in order to minimalize the rate of complications that may appear. We present from "Cuza-Vodă" Clinical Hospital of Obstetrics and Gynecology from Iasi, the case of a 30-year-old pregnant woman with dichorionic-diamniotic twin pregnancy, barrier of MHV, who suffered postoperative bleeding complication under guidelines recommended doses of anticoagulant. The hematoma that developed five days after the caesarian section need it surgical intervention for hemostasis correction. **Conclusions:** The incidence of bleeding complications is higher during pregnancy and postpartum in MHV carriers. Thrombosis or hemorrhage usually occur when the monitoring of anticoagulation is improper or when the treatment must be interrupted for different reasons. **Keywords:** ANTICOAGULANT DRUGS, HEART VALVE PROSTHESIS, PREGNANCY.

Valvular heart disease represents the most widespread entity of cardiovascular pathologies among pregnant women, having the most ordinary etiologies, such as congenital heart conditions and rheumatic heart disease (1).

A brittle issue represents the management of women with mechanical heart valves (MHV) during pregnancy and per partum period. Over the years, the development of pharmaceutical industry and technological fields improved the usage of anticoagulants and biocompatibility of the MHV. By increasing the adhesion of a slender biomaterial layer to the biocompatible surface of the mechanical valves, the feasibility of MHVs augments, decreasing the rate of thrombosis complications (2-4).

The management of valvular heart diseases has developed tremendously, improving the quality of life for the population with congenital or acquired cardiac diseases. Therefore, the birth rate between fertile women with MHV is continuously increasing and requires more improvements regarding the control of anticoagulation (CA) among pregnancy (5).

Pregnant women with MHV present a significant risk of mortality and morbidity, with raised costs for their management as the oncology patients. Obstetrical complications are very common in the per partum period and often include postpartum hemorrhage (PPH), wound hematoma or intra-abdominal hemorrhage. The management must be multidisciplinary, made by a maternal-fetal medicine specialist, a cardiologist, a hematologist, an anesthesiologist, and a nursing personnel experienced in obstetrics and cardiology, in order to consider and handle the risks and benefits for every patient (5).

CASE REPORT

A 30-year-old Caucasian women, 72 kg, 172 cm, pregnant III, para III with dichorionic–diamniotic twin pregnancy of 36 weeks + 2 days (first fetus – complete breech presentation; second fetus – transverse presentation) known with intrahepatic cholestasis of pregnancy was admitted to the Obstetrics Department of "Cuza-Vodă" Clinical Hospital of Obstetrics and Gynecology from Iasi, complaining for non-systemic uterine contractions. Her medical history revealed two anterior caesarean sections, MHV, heart failure NYHA class II, chronic venous insufficiency, and atrial septal defect closure which required surgery at young age. Clinical examination at that moment was found normal. The pathologic results of patient`s blood test revealed: ALT= 56 U/L, AST= 47 U/L, Serum Bile Acids= 27.0 μmol/L, Fibrinogen= 522 mg/dL and INR= 0.97.

One month before, the patient performed a cardiologic examination and echocardiogram. The results shown a preserved systolic function of the left ventricle, without segmental kinetic disturbance, normal ejection fraction, mild tricuspid regurgitation, no signs of pulmonary hypertension and normal quantity of pericardial fluid. The patient was under treatment with Acenocoumarol 4 mg per day during the pregnancy and switched it to Enoxaparin 8000 UI/0.8mL x 2 / day, as the cardiologist recommended.

Two days after, she was admitted to Intensive Care Unit, having systematic uterine contractions, and the caesarean section was perform without any bleeding complications or others. The patient gave birth to twin who weighed 3,100 g, respectively 3,300 g, both of them having 7 Apgar score at 5 minutes. The bacterial endocarditis prophylaxis was made and in postpartum period the patient was treated with Cefuroxime 1.5 g/12 hrs, Enoxaparin 7,000 UI/0.7 mL and 6,000 UI/0.6 mL/24 hrs., and anti-inflammatory drugs. The next day after surgery, the coagulation parameters were found within normal values.

In the 5th day, the patient accused high intensity pain in the hypogastrium. Her clinical examination revealed a tendered and distended lower quadrant; a round, rough consistency mass (15 cm diameter) was noticed between the two abdominal flanks. Abdominal ultrasound revealed a normally decreased uterine size without any retention of placenta or membranes fragments and a hypoechoic area measuring 150 x 100 mm, being suggestive for preper-

itoneal hematoma (fig. 1). Blood tests were abnormal within WBC=13.88 10^3/uL, NEU=11.5 10^3/uL, HGB= 7.5 g/dL, HCT= 22.4%, CRP= 96 mg/L, Fibrinogen= 647 mg/dL.

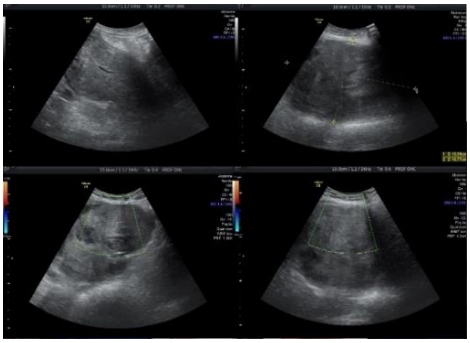

Fig. 1. Abdominal ultrasound examination of the uterus and hypoechoic mass measuring 15/10 cm suggestive for preperitoneal hematoma after cesarean section

Surgical treatment was performed in order to evacuate the preperitoneal hematoma and to establish the hemostasis. Intraoperative, it was found preperitoneal organized blood clots and approximately 1,000 mL of dark blood (fig. 2). A good hemostasis was obtained with no intraoperative complications. Postoperative, the patient went under treatment with Enoxaparin 6,000U/ 0.6 mL/12 hrs., Metronidazole 500 mg/100 mL, and Cefuroxime 1.5g/12 hrs. Three days after the intervention, the patient change Enoxaparin anticoagulant therapy with Acenocoumarol 4 mg 3 tb/day. Blood test results shown: HGB= 8.5 g/dL, HCT= 16.2%, aPTT= 31.1, D-Dimer tests= 200-400 ng/mL, Fibrinogen= 681 mg/dL, Quick time= 14.6/sec, INR= 1.09, IQ= 93, ISI= 1.24.

The postoperative patient's evolution was favorable, without any other bleeding complications. In day she went out the hospital her vital signs were stable and blood test in physiologic parameters.

Fig. 2. Massive (subaponeurotic) preperitoneal hematoma

DISCUSSION

In the presented case, the patient was under VKA (Vitamin K Antagonists) since the beginning of pregnancy and switched to 8,000 UI/0.8 mL Enoxaparin, twice per day, one month before the admission in the Obstetric Department, as the cardiologist recommended. Among the pregnancy, no bleeding or thrombosis episodes and no signs of fetal toxicity were reported. During the surgery, the intraoperative bleeding was normal with no hemorrhagic episodes and a rigorous hemostasis was performed. In postpartum, the anesthesiologist reduced the anticoagulant doses to 7,000 UI/0.7 mL and 6,000 UI/0.6 mL, respectively, per 24

hours. Even though the coagulogram parameters were within normal before and post-surgery, in the 5th day after the C-section the patient developed a large hematoma that need it reintervention.

The optimal dose of anticoagulant should be establish in a manner to create a balance between the risk of hemorrhage and thrombosis (fig. 3). After the second intervention, the Enoxaparin was reduced again to 6,000 UI/0.6 mL every 12 hours and three days after was switch to 4 mg of Acenocoumarol/day, with no further bleeding or thrombosis episodes.

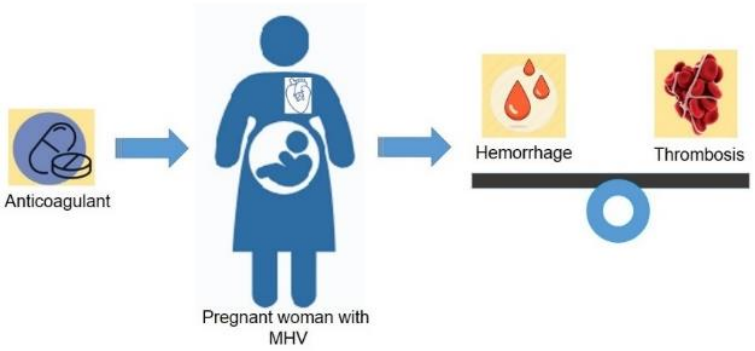

Fig. 3. The expectant response of optimal dose of anticoagulant treatment in pregnant women with MHV

The flawless anticoagulant indicated in pregnancy should be safe for the fetus, to not cross through hemato-placental barrier, in order to avoid fetal hemorrhage and teratogenicity. Vitamin K antagonists, unfractionated heparin and low-molecular-weight heparin represent the allowed anticoagulant drugs for pregnant patients who carry MHVs, even though all these treatment classes are associated with feto-maternal adverse events (6).

VKA are teratogenic drugs that cross the hemato-placental barrier, causing osseous and cartilaginous maldevelopment as well as anomalies of the central nervous system. It must not be administered between 6 and 12 gestational weeks due to its higher risk of embryopathies (7). Its fetal risk outcomes depend on the dose that is administered, usual ≤ 5 mg of warfarin per day has a reasonably safer profile (8).

European Society of Cardiology (ESC) guidelines and American Heart Association (AHA)/American College of Cardiology (ACC) advise VKAs sequel during pregnancy at the lowest doses with the administration under strict control of UFH (Unfractionated Heparin) or LMWH (Low Molecular-Weight Heparin) between 6-12 gestational weeks period. To what regards the birth plan, natural delivery is common advisable. Cesarean section is recommended when is need it to deliver rapidly due to the obstetrical indications or in a full VKA anticoagulated patient with premature labor in order to decrease the risk of fetal intracranial hemorrhage during vaginal delivery. Interruption of VKA and induction of intravenous UFH (requires an activated partial thromboplastin time– aPTT –more than two

times followed) or LMWH (requires a target of anti-Xa level between 0.8-1.2 U/mL, every 4-6 hours after de administration) should be initiated with 2 weeks anterior the planned vaginal birth due to the risk for premature labor. Low-molecular weight heparin must be changed with UFH before delivery, whilst UFH should be administrated during the labor and restarted after 4-6 hours the delivery happened (9, 10).

A meta-analysis, conducted by Steinberg *et al.* (2017), found that VKA therapy experienced the most decreased rate of adverse maternal effects compared with LMWH which presented the lowest risk for adverse fetal effects. Also, they observed an equivalent fetal risk in women treated with ≤ 5 mg of warfarin per day and those who received LMWH (11). Another study reported that VKAs encounter the smallest rate of maternal complications and live births, whereas LMWH associate the highest rate of live births (12).

Bleeding complications are quite frequent when anticoagulation therapy is used. Cardiology Registry of Pregnancy and Cardiac Registry (ROPAC) showed 23% rate of bleeding complications whilst United Kingdom Obstetric Surveillance System (UKOSS) study presented a higher rate, up to 29% (13, 14). In some situations, the warfarin therapy can be delayed to prevent PPH but requires a careful obstetric monitoring. Patients with MHV present low pregnancy outcomes, especially when high doses of warfarin are administered in the first trimester of pregnancy. It was reported an increased rate miscarriages, stillbirths, neonatal death, preterm labors, and certain fetal abnormalities. Bleeding complications can be hard to control in gynecology pathologies (15) and it becomes more complicated when the patient associates an MHV due to a cardiovascular disease.

Thus, the results we are presenting here on this gynecological-cardiovascular multidisciplinary context could have a further relevance in these complex pathophysiological approaches, as this could be an important management strategy for cases like this, as our team demonstrated in previous related works (16-18).

In our case, the patient had a favorable prognosis after second time reduction of the anticoagulant therapy. The increased dose of Enoxaparin and a rigorous monitoring prevented another episode of hemorrhage. Although the patient received the correct doses of anticoagulant, according to her weight and associate pathology, as the guidelines recommend, she still manifested hemorrhagic complication, reaching the conclusion that a rigorous monitoring is necessary even under a correct therapy.

CONCLUSIONS

Pregnant women who carry mechanical heart valve acquire an increased risk to develop thrombotic or hemorrhagic complications, and chronic anticoagulation is need it, but the long-term anticoagulation needs to be safe for both mother and fetus.

LAPAROSCOPY IN ACUTE ABDOMINAL DISORDERS (Abstract): In emergency preoperative diagnosis is most accurate in acute cholecystitis and least accurate in pelvic conditions and mesenteric ischemia. Laparoscopy has a double goal: establish or confirm diagnosis and treating the disorders. Laparoscopy identifies those patients who do not need surgery. Our experience includes 2,778 patients with surgical acute abdomen: 1,857 cases with acute cholecystitis, 719 cases with acute appendicitis, 57 cases with perforated peptic ulcer, 10 cases with intestinal obstruction on postoperative adhesions, 19 cases with abdominal trauma, 87 cases with acute adnexal pathologies, 4 cases with acute pancreatitis, 12 cases with mesenteric ischemia, 12 cases with abdominal abscesses and one case with false acute abdomen. Our experience clearly shows the feasibility and safety of the laparoscopic appendectomy. The minimal access approach brings back suture in the treatment of perforated peptic ulcer in the conditions of an efficient postoperative medical treatment. Keywords: LAPAROSCOPY, ACUTE ABDOMEN, UNNECESSARY LAPAROTOMIES.

The recent expansion of both diagnostic and therapeutic laparoscopy has added a new tool to the surgical armamentarium. Laparoscopy is an efficient method for diagnostic in surgical acute abdomen because usually allows a good view of the uterus and adnexa, the appendix, the gallbladder, the stomach, the pylorus, and the first portion of the duodenum.

The laparoscope was introduced to determine whether the laparotomy would be required. With the development of new techniques, it has become possible to perform definitive therapeutic procedures under videoendoscopic control in the setting of the acute abdomen.

Laparoscopic appendectomy and closure of perforated duodenal ulcer have become common procedures, and laparoscopic cholecystectomy is now the standard of care in acute cholecystitis.

Laparoscopy can be used to assess intestinal viability if bowel ischemia is suspected.

MATERIAL AND METHODS

Between January 2013 and March 2020, in the First Surgical Clinic, from "Sf. Spir-

idon" County Clinical Emergency Hospital, Iasi were performed 8,367 laparoscopic interventions; 2,778 interventions of these (33,2%) were performed in emergency.

Laparoscopies establish the following diagnostic: Perforated peptic ulcer – 57 cases; Abdominal trauma – 19 cases; Intestinal infarction – 12 cases; Intestinal obstruction – 10 cases; Acute appendicitis – 719 cases; Acute adnexal pathologies – 87 cases; Acute cholecystitis – 1,857 cases; Acute pancreatitis – 4 cases; abdominal abscesses – 12 cases; False acute abdomen – 1 case.

RESULTS

8031 laparoscopic cholecystectomy was performed in our clinic for various anatomoclinical form of cholecystitis. Laparoscopic cholecystectomy for acute cholecystitis was performed in a series of 1857 patients (71.9% women and 28.1% men) with mean age 50.4 years (between 18 and 82 years). Obesity was encountered in 78% of the cases. Clinical aspect was typical for acute cholecystitis in 93.7% of the cases. In all cases diagnosis was confirmed or suggested at ultrasound examination. In most cases acute cholecystitis was related to gallstones presence; only 5.7% of the cases were not determined by lithiasis.

At pathology, the lesions were: edematous acute cholecystitis (72.3%); phlegmonous acute cholecystitis (8.1%); gangrenous acute cholecystitis (9.5%); plastron (11,1%).

Intraoperative in 80% of the cases we found pericholecystic adhesions. In 31.2% Hartmann pouch was placed behind porta hepatis. This was not surprising because with an inflamed gallbladder the anatomy in the area may be severe distorted. If the dissection was difficult or the ductal anatomy was not clear we converted to open cholecystectomy, because in this conditions the risk of ductal lesions is rather high. Conversion rate in this series was 9.1% (169 cases) as compared to a 2.8% rate in the entire series of laparoscopic cholecystectomies. The rate of biliary lesions was 0.1%.

Decompression of the enlarged gallbladder was needed in 80% of the cases.

We encountered the following intraoperative complications: gallbladder perforation (31.8%); hemorrhage (16.8%); gallstone loss (11.2%).

Mean operating time was 78 minutes (25-130 minutes), much longer than the mean value for laparoscopic cholecystectomy in general. Bottom line is that the intervention was easy in only 7.8% of the cases. In most cases we gave antibioprophylaxis. Postoperative morbidity was low, 5.6%. Mortality was 0.18% (2 cases – the cause was pulmonary thromboembolism). Mean postoperative hospitalization was 3.8 days. Laparoscopic cholecystectomy can be performed routinely for acute cholecystitis. Laparoscopic appendicectomy was performed on a series of 719 patients (81% women and 19% men). Their age was between 12 and 68 (mean 23) years.

Laparoscopic appendicectomy was indicated in the following situations: women at the reproductive age, because of the difficulties of establishing an accurate preoperative diagnosis in their cases; in our series the diagnosis error rate in this group was 20%; obesity, present in 32% of the cases; young patients; sportsmen.

At pathology, the lesions were: edematous appendicitis (61.5%); phlegmonous appendicitis (25.3%); gangrenous appendi-

citis (7.6%); plastron (5.6%).

The technique used was: "in" in 120 cases (16.7%); "out" in 252 cases (35%) and mixed in 298 cases (41.49%). Conversion rate was 6.81% (49 cases).

Morbidity was: 4 cases with parietal hematomas (0.55%); 5 cases with wound infections (0.69%).

Complications encountered were: 2 cases with peritonitis (6th day postoperative) 0.27%. Mean hospital stay was 3.2 days.

In our experience laparoscopic appendicectomy has certain advantages allows diagnosis of other conditions; decreases wound infection rate; deceases hospital stay; decreases recovery time for the patient; best cosmetic results.

Laparoscopic closure of duodenal peptic ulcer was performed in a series of 57 patients (all men) with mean age 28 years (between 18 and 58 years). The presentation was at 1-10 hours after symptoms onset. Preoperative diagnosis was perforated ulcer in most cases, pneumoperitoneum being present in 55 cases. At presentation, the patients had acute abdomen symptoms; perforations were small (< 5 mm) in all cases. Suture closure with an omental patch was performed in 57 cases. It is very important to wash and drainage very well the peritoneal cavity. Laparoscopic intervention offers this possibility. In only one case an inadequate closure leaded to a leak and after two days we performed a classic intervention. There were no other complications, and the morbidity was zero. Mean postoperative hospitalization was 4.6 days. Postoperative all patients received medical treatment for ulcer and sterilization of *Helicobacter pylori*. At follow-up after 3 months and a year there was no recurrent peptic ulcer in all cases.

Open laparoscopy was performed in 10 cases of intestinal subacute obstruction by postoperative adhesions. In only 5 cases was possible to performed adhesiolysis. In all other cases we had to convert to open procedure.

Laparoscopic surgery for abdominal trauma was performed in 19 cases, 5 cases for wound trauma and 14 cases for abdominal blunt trauma (hemoperitoneum). In abdominal blunt trauma intraoperative diagnosis was 3 hepatic lesions (II-III Moore degree) for who was performed exploration and hemostasis with Argon beam and TachoComb® (superficial injury of the liver) and 11 splenic lesions (II-III Moore degree) for who we performed laparoscopic splenectomies in 3 cases (rupture hematoma spleen), laparoscopic diagnosis with conservative treatment and spleen preservation in 2 cases and 6 conversions with spleen preservation in one case (packing with resorbable prosthesis).

Laparoscopic procedures were performed for acute adnexal pathologies in 87 patients. In cases with torsion of the ovary was required oophorectomy. In 6 cases with tubal pregnancies, we performed 3 salpingostomy and 3 salpingectomy, respectively. Otherwise, there were cases of ruptured ovarian cysts hemorrhagic. We did not include cases of pelvic inflammatory disease.

Other causes of acute abdomen in which we intervened by means of laparoscopy were: 4 cases of acute pancreatitis and 10 cases with bowel ischemia. In all this 4 cases an open laparotomy was avoided.

DISCUSSION

Many of the causes of the acute abdomen can be managed by laparoscopic ap-

proach (1). The therapeutic approach in these patients is based on clinical suspicion and on the results of diagnostic laparoscopy. Each procedure started by performing diagnostic laparoscopy to determine the specific abnormality present. Laparoscopy has become a routine procedure in the management of acute abdominal disease and can be considered both an excellent therapeutic and additional diagnostic tool in selected cases (2).

The diagnostic of acute cholecystitis is usually made preoperatively by clinical examination and ultrasound exploration. Sometimes acute cholecystitis may present as an acute abdomen if the gallbladder is gangrenous or perforated. Grasping of the gallbladder can be difficult when an acute state is present. We do not hesitate to decompress the gallbladder to improve the ability to grasp an acute inflamed gallbladder.

Laparoscopic cholecystectomy can be routinely performed in acute cholecystitis, but the surgeon must be prepared to convert to open cholecystectomy. If there is necrosis or the gallbladder cannot otherwise be retracted, then the operation should be converted to open approach.

It is also important to not spend to long with the laparoscopic technique if the dissection is difficult or the ductal anatomy is not clear.

The complications are more frequent in laparoscopic cholecystectomy than in open method. Bleeding from the liver can be a significant problem. Bile leaks can occur the cystic duct where a clip has fallen off.

Endoscopic retrograde cholangiopancreatography is used to identify the site of the ductal leak and to rule out injury to the common bile duct.

Common bile ducts injuries typically occur when the common duct or the right hepatic duct have been misidentified as the cystic duct. This injury is preventable by performing meticulous dissection beginning at the junction of the neck of the gallbladder and the cystic duct.

Indications for laparoscopic appendectomy include patients with an uncertain diagnosis (elderly, reproductive age females), obese patients, and those with suspected perforated appendicitis.

Laparoscopic management of perforated appendicitis is superior to open technique.

Dissection of adhesions and the irrigation of the entire abdominal cavity can be realized without extension of the incision. Simultaneously, another cause of acute abdomen can be identified and operatively managed. Obese patients have an increased wound infection rate and require larger incisions for open procedure. Further advantages of the laparoscopic technique include decreased exposure of subcutaneous tissue to the infected appendix and therefore a lower infection rate (3). It is better to performing appendectomy even if the organ appears normal (sometimes the appendiceal inflammation can be detectable only at the microscopic examination).

The preoperative diagnosis of perforated peptic ulcer is usually simple established by clinical examination and presence of air in peritoneal cavity on the abdominal radiographic films. The laparoscopic approach brings back the suture closure with an omental patch in the treatment of perforated duodenal ulcer. The modern medical treatment of peptic ulcer avoids the recurrent ulcer.

If the perforation is small and surrounding tissue is healthy it is possible to per-

formed direct closure using 3-0 polyglactin suture closure on atraumatic needles. It is better to close the defect in a transverse direction to prevent narrowing of the lumen.

Large perforations or those with large amount surrounding tissue friability and edema can be closed with an omental plug. The peritoneal cavity must be thoroughly irrigated with warm saline solution. Tilting the table in different positions helps with irrigating the entire peritoneal surface (4).

"Kissing ulcers" can occurs in which there is an anterior perforation and posterior penetration with bleeding. In these conditions it may be necessary to convert to laparotomy.

Acute abdominal pain from gynecologic sources is a common problem in surgery. The etiology of this pain in reproductive age females is often obscure (5). Many of these gynecologic sources of acute abdominal pain can be managed laparoscopically. Laparoscopy is indicated when the diagnosis is uncertain, the patient is obese, and the definitive operative management can be handled with the laparoscopic technique. The only contraindication is the patient with hemorrhagic shock.

Another cause of acute abdomen can be the acute pancreatitis. The laparoscopic diagnosis is made by opening the lesser sac with scissors dissection.

Ischemic bowel can be found at laparoscopy for an acute abdomen. It depends on the judgment of the surgeon to determine if it is hopeless situation (6). If the bowel is ischemic and not necrotic, the patient should have emergency mesenteric angiography.

The use of laparoscopy in blunt abdominal trauma has been expanded from merely a diagnostic tool to a therapeutic modality in selected cases (7). This has resulted in a quicker and more specific diagnosis and avoidance of unnecessary laparotomies.

Regarding the outcome measures for cases of the acute abdomen as a whole, Agresta *et al.* (8) included 1,272 patients admitted with acute abdomen who were approached laparoscopically. In comparison with open surgery, there was a significant reduction of total complication in laparoscopic treatment than open surgery (1.9 *vs.*13%).

Hemodynamic instability, huge abdominal distension, fecal peritonitis, and perforated cancer are relative contraindications for the laparoscopic approach. In recent years, abdominal emergencies have increasingly been managed successfully by laparoscopy. In acute appendicitis, acute cholecystitis and perforated peptic ulcer, randomized controlled trials have proven that the laparoscopic approach is as safe and as effective as open surgery, with fewer complications and a quicker postoperative recovery. Other indications such as blunt and penetrating trauma to the abdomen, small bowel occlusion and perforated diverticular disease are under debate, indicating that more randomized controlled trials comparing laparoscopic and open surgery are still necessary (6).

CONCLUSIONS

Laparoscopy is very important in the diagnosis and treatment of acute abdomen conditions. This is due to certain advantages as the ability to examine the entire peritoneal cavity and perform a definitive procedure, and of course when needed there is always the possibility to convert to an open procedure. Laparoscopy also reduces unnecessary laparotomies.

NEWS

LONG TERM CONTROL IN ACROMEGALY - IS IT ACHIEVABLE?

Acromegaly is a rare endocrine disorder characterized by an excessive chronic secretion of GH and IGF-I, that, in time, results in numerous comorbidities. Biochemical control is not easily achievable but is of paramount importance for a reduction in morbidity and mortality. The presented results come from an extension to a prospective, multicenter, randomized, parallel-group, 6-month core study (Phase III PAOLA study). In the core study, patients were randomized to double-blind long-acting pasireotide 40 mg/28 days or 60 mg/28 days, or continued treatment with open-label long-acting octreotide 30 mg or lanreotide 120 mg every 28 days. As much as half of the enrolled patients had at least three comorbidities (mostly cardiovascular and glucose- or lipid-related disorders) at study entry. The conclusion of this study is that long-acting pasireotide was an effective and consistent therapeutic option for up to 5.8 years of treatment in patients with previously uncontrolled acromegaly and a high prevalence of comorbidities (cardiovascular, metabolic, including glucose-related disorders). (Colao A, Bronstein MD, Brue T, *et al*. Pasireotide for acromegaly: long-term outcomes from an extension to the Phase III PAOLA study. *Europ J Endocrinol* 2020; 182(6): 583-594).

PONSETI METHOD AS A TREATMENT OPTION FOR NEGLECTED CLUBFOOT. CASE REPORT AND LITERATURE REVIEW (Abstract): Congenital clubfoot is a common congenital malformation, whose conservative treatment using the Ponseti method achieves excellent initial correction rates and good long-term results. On the other hand, neglected clubfeet, which are typically more frequent in underdeveloped and developing countries, pose treatment difficulties and render corrective surgery necessary. The main problems with correction are raised by the increasing stiffness present in the soft tissues and the dysplastic development of bones. Furthermore, the hyperlaxity of young children decreases with growth, contributing to the reduced overall elasticity of the affected soft tissues and clubfeet. Deciding upon which type of treatment would be appropriate is not always facile. In our clinic, we tend to start the treatment of neglected clubfeet with the modified Ponseti method, which can achieve partial correction or full correction in most cases, diminishing the need for extensive surgical procedures. The case report of a long time neglected bilateral clubfoot successfully corrected using the modified Ponseti method is presented below, followed by a relevant review of the literature. **Keywords**: NEGLECTED CLUBFOOT, STIFF CLUBFOOT, LATE PRESENTING CLUBFOOT, POST IMMOBILIZATION FRACTURE, POST-IMMOBILIZATION OSTEOPOROSIS.

Congenital talipes equinovarus is a frequent congenital malformation with an incidence of 1-2 cases per 1,000 births in Europe (1-3). Most clubfeet are idiopathic as the etiology is still unknown and they should be distinguished from syndromic clubfeet occurring in association with neuromuscular diseases, genetic syndromes, teratogen-induced malformations. Regardless of etiology, the diagnosis of clubfoot remains clinical, and it is based on the presence of four deformities which are almost always present: cavus, adductus, varus and equinus. The treatment of clubfoot is usually done before walking age and the Ponseti method (4), which is the gold standard, achieves correction in over 90% of the cases (5, 6). In these cases, surgery is reserved for resistant clubfeet and treatment of recurrences and residual deformities. Neglected clubfeet are defined as those clubfeet diagnosed and treated after walking age, which are more difficult to treat due to increased stiffness. Probably manipulative treatments have been

tried as initial treatment, but surgery remains the main method for their correction so far, especially in those severe cases which were neglected for a long

Fig. 1. Clinical aspect of neglected clubfeet before, during (swelling around the ankle and medial side of the foot were present during treatment and disappeared completely until the end of treatment) and after treatment (clinically moderate persistent cavus in the right foot).

CASE REPORT

We present the case of an 8-year and 11-month-old boy referred to our clinic for severe bilateral deformation of the feet associated with difficulty in maintaining balance during walking. Informed consent was obtained from his legal guardians. According to his parents, the deviations started developing progressively in both feet at the age of 2.5-3 years. The reason for the late presentation was his medical history, which included: growth delay of undetermined cause, extragonadal stage IV germ cell tumor of the left internal obturator muscle with pulmonary metastases treated by resection and chemotherapy (in complete remission at presentation), pulmonary emphysema, and post-thrombotic syndrome of the left common and internal iliac veins, both of which apparently developed during oncological treatment. Electromyography revealed a peripheral axonal demyelination in both lower limbs suggestive of severe sensory and motor polyneuropathy, further diagnostic studies being required. Clinical examination revealed severe stiff clubfeet, both graded Pirani 4 and Dimeglio grade IV, bilateral calf hypotrophy; calluses on the dorsolateral aspect of both feet; bilateral *genu flexum*, and no active toe extension. As

treatment, we used the modified Ponseti technique (7) which practically follows the same steps as the original Ponseti method, except the cast change interval (every two weeks). Due to patient's medical history, we prescribed Enoxaparin 2,000 IU per day for the deep vein thrombosis (DVT) prophylaxis during the casting period. In-between cast change interval, the patient routinely underwent Doppler ultrasound examination of both limbs and pelvis in order to exclude occult DVT. The duration of the correction phase was 14 weeks, and we applied a number of 6 casts according to the modified Ponseti Protocol (fig. 1). The cavus deformity was corrected during the first 4 weeks (2 casts), while the adductus and varus deformity were corrected in the following 6 weeks (3 casts). Lastly, the equinus deformity was corrected by performing a percutaneous Achilles tenotomy under general sedation and local anesthesia due to patient's history of pulmonary emphysema, achieving approximately 10 degrees of dorsiflexion bilaterally. The patient was immobilized in a long-leg plaster cast for 4 weeks maintaining the foot in dorsiflexion and abducted to approximately 60 degrees. After last cast removal, we prescribed a full-time foot ankle abduction orthosis for the following 3 months, but the patient had a hard time tolerating it.

Full-weight bearing was allowed only after 4 weeks due to the osteoporotic appearance of bones on the X-rays taken at the end of the correction phase (fig. 2).

The improvements of the clubfeet during the correction phase were slow but encouraging. Nevertheless, starting with week 4 of the correction phase the patient complained of occasional pain at the level of the talar head and anteromedial aspect of the ankle joint during immobilization (counterpressure point). The pain typically disappeared the same day. Several days after weight bearing during physical therapy, the patient described pain in the middle third of the right calf, which disappeared completely after one month. The X-rays taken 8 weeks later showed the presence of a healed stress fracture of the tibia and fibula, with no misalignment (fig. 3).

Fig. 2. Anteroposterior X-ray of the feet before tenotomy showing osteoporotic appearance in both feet, normal talocalcaneal relationship, well-reduced navicular covering the talar head.

Fig. 3. Weightbearing lateral X-ray of the right lower leg.

Healed diaphyseal stress fractures of the right tibia and fibula two months after weight bearing was permitted. Plantigrade aspect of the foot.

DISCUSSION

The purpose of clubfoot treatment is to obtain a plantigrade, functional, painless foot, which we achieved in the end (fig. 1). To our knowledge, this is the first published case report of a secondary neglected clubfoot treated with the Ponseti method. In this particular patient, the associated comorbidities were the main reason for the late presentation. Furthermore, had a corrective surgical release been chosen as a treatment option, anesthesia would have carried more risks due to our patient's associated conditions. Surgery is still the first option of treatment in many countries despite the fact that it is technically more difficult, carries more risks of complications, is more painful and more expensive (8-10).

Starting with the worldwide adoption of the Ponseti method as first option in clubfoot treatment, the age interval for using this method has increased. Usually, the mean age at treatment initiation is between 2 and 5 years, but children of older age can be found dispersed in the literature throughout different published studies (9, 11, 12). Correction rates ranging from 67% to 100% have been reported using the Ponseti method, without associated extensive surgery, which is remarkable taking into consideration that almost all neglected clubfeet are very stiff and severe (7, 13, 14). The mean age at presentation and mean number of biweekly applied casts found in the literature is similar to ours: 3 to 4 months and 7 to 12.8 casts (7, 13). The dorsiflexion range obtained after tenotomy tends to diminish in older children (13), but it is still compatible with a plantigrade foot and ability to wear normal shoes, so the family is generally satisfied with the result. Although in his initial study Lourenco (7) maintained the post-tenotomy plaster for 5 weeks to allow healing of the Achilles tendon, other authors did not encounter any complications regarding Achilles tendon healing after a 4-week post-tenotomy immobilization (13, 15). Regarding the bracing protocol used to prevent recurrences, most authors prescribe it for one year in case of children older than 4 years. However, as in the case of our patient, tolerance to bracing might be reduced in older children, hence compliance rates may diminish. Different dermatologic reactions like swelling and skin erythema (fig. 1) might be seen during the correction phase and are thought to be caused by excessive pressure, but they are usually mild and do not need treatment. On the other hand, osteopenia induced by long periods of immobilization is a concerning aspect as it increases the risk of iatrogenic fractures. They are considered to have a risk incidence of 1.3% in children younger than 3 years whose feet are forcefully manipulated (16). Besides this aspect, as seen in our case report (fig. 2), osteoporosis may facilitate the development of stress fractures during weight bearing even when precautions are taken.

CONCLUSIONS

Although surgical treatment is probably the first choice of treatment in patients with neglected clubfeet in many pediatric orthopedics centers, the modified Ponseti technique shows encouraging results and is worth to be taken into consideration as a treatment option. We believe this modified manipulative method can at least partially correct the deformities in most cases, reducing the extent of further surgical procedures required to complete the correction.

CONFLICT OF INTERESTS AND FUNDING

The authors declare that there is no conflict of interest and they received no specific funding regarding this scientific research.

EPIDEMIOLOGY OF PURULENT-SEPTIC INFECTIONS CAUSED BY METHICILLIN-RESISTANT *STAPHYLOCOCCUS* IN THE REPUBLIC OF MOLDOVA **(Abstract):** *Staphylococcus* infections are a major global concern, caused by the annual growth of methicillin-resistant *Staphylococcus* strains and the emergence of strains resistant to reserve anti-staphylococcal antibiotics. **Aim:** The aim of the study was to determine the risk factors, the degree of spread of methicillin-resistant *Staphylococcus* (MRS) strains in health care facilities in the Republic of Moldova, as well as their resistance to antibacterial drugs. **Material and methods:** The research of the real incidence, epidemiological peculiarities and the degree of sensitivity/resistance of MRS infections to antibiotics was performed based on the descriptive cross-sectional observational epidemiological study, overall being analyzed 10,055 staphylococcal strains. The risk factors and socio-economic impact were determined based on a retrospective case-control study. The research group included 269 patients with bacteriological investigations positive for methicillin-resistant *Staphylococcus* (MRS), the control group - 159 patients with bacteriological investigations positive for methicillin-sensitive *Staphylococcus* (MSS). **Results:** The share of MRS strains among *Staphylococcus* strains in the Republic of Moldova is on average 35.97%. A higher level of spread of MRS strains is recorded in maternity hospitals - 61.81%, followed by multi-profile health care facilities - 36.32%, slightly lower in rural health care facilities - 22.36%. The prevalence of MRS strains varied depending on the profile of departments and pathological products. Most often, MRS strains were isolated from patients in the departments of surgery, traumatology, orthopedics, resuscitation and intensive care. A high level of MRS was found in blood cultures - 76.11%, and 96.3% of MRS strains isolated from blood proved to be polyresistant. **Keywords:** HEALTHCARE-ASSOCIATED INFECTIONS, METHICILLIN-RESISTANT *STAPHYLOCOCCUS*, METHICILLIN-SENSITIVE *STAPHYLOCOCCUS*, POLYRESISTANCE, ANTIBIOTICS.

Healthcare-associated infections caused by antimicrobial-resistant microorganisms are today one of the most important challenges for modern medicine. There are 426,277 healthcare-associated infections in the EU each year caused by antimicrobial-resistant microorganisms, the number of deaths being estimated at 33,110 per year (1, 2).

Currently, *Staphylococcus* infections are mostly produced by multidrug resistant strains to a very wide range of antibiotics used in the inpatient setting (2, 3).

As the last decades have been marked

by a progressive and rapid increase in the number of resistant bacterial strains involved in human diseases and a low rate of introduction of new antibiotics into therapy, in 2017, the WHO established the most important categories of multidrug resistant germs which require the introduction of new therapeutic strategies, with 3 priority levels: critical, high and medium, the methicillin-resistant *Staphylococcus aureus* (MRSA) strains belonging to the high level (4, 5).

Staphylococci which rank first in the etiology of bacterial infections, the annual increase in the number of methicillin-resistant staphylococcal strains and the emergence of strains resistant to reserve anti-staphylococcal antibiotics, place this infection among emerging infectious diseases (2, 6, 7, 8).

From the first cases of MRSA to date, the scale of the problem has increased dramatically, the incidence of MRSA infections reaching endemic proportions in some hospitals. In Europe, a north-south gradient is observed, MRSA strains being rare in Scandinavian hospitals (<2%) and much more widespread in hospitals in Mediterranean countries (> 40%) (9, 10, 11, 12).

Although in recent years there has been a decrease in the percentage of methicillin-resistant *Staphylococcus* strains in the EU/EEA, from an average of 19.6% in 2014 to 16.9% in 2017, MRSA remains a major pathogen in the EU/EEA, MRSA levels being high in several countries, and resistance to many antimicrobial groups is steadily increasing (12).

Knowledge of risk factors, transmission mechanisms and local epidemiology in methicillin-resistant *Staphylococcus* (MRS) infections will contribute to the implementation of surveillance and control measures as well as to the improvement of the given recommendations.

MATERIAL AND METHODS

The research of the real incidence, epidemiological peculiarities, nosological forms and the degree of sensitivity/resistance of MRS infections to antibiotics was performed based on the descriptive cross-sectional observational epidemiological study. The study included the results of bacteriological investigations of patients with purulent-septic infections (PSIs) from two multi-profile health care facilities over a four-year period, 2014-2017, as well as from a maternity hospital and the results of bacteriological investigations of patients in rural areas (on the model of three districts).

A total of 10,055 *Staphylococcus* strains were analyzed, 8,639 being isolated from multi-profile health care facilities, 1,090 from rural areas and 326 from a maternity hospital. Isolation of *Staphylococcus* strains and determination of methicillin resistance and antibiotic resistance / sensitivity were performed both by the classical method and the automated VITEK 2 Compact system (bioMérieux).

To determine the risk factors and the socio-economic impact, a retrospective case-control study was performed, based on the survey data collected from patient observation forms with PSIs caused by staphylococci. Two research groups were created: the basic group included patients with bacteriological investigations positive for MRS and the control group comprised patients with bacteriological investigations positive for MSS.

RESULTS

Resistance of *Staphylococcus* strains to antibacterial drugs varied depending on the

group of antibiotics, the type of antibiotic and the profile of the inpatient department where it was isolated. The highest prevalence of methicillin-resistant *Staphylococcus* was found in maternity hospitals, in which, of the total number of isolated *Staphylococcus* strains, 61.81% were found to be MRS, followed by multi-profile health care facilities, with a share of MRS strains of 36.32%, and slightly lower in rural areas - 22.36% (fig. 1).

The situation regarding PSIs caused by MRS in the health care facilities of the Republic of Moldova in the multiannual dynamics is worsening. The share of MRS strains isolated from patients with PSIs during 4 years of studies is increasing, from 29.62% in 2014, to 42.70% in 2017, the increase being statistically significant ($t = 5.17$, $p<0.001$) (fig. 2).

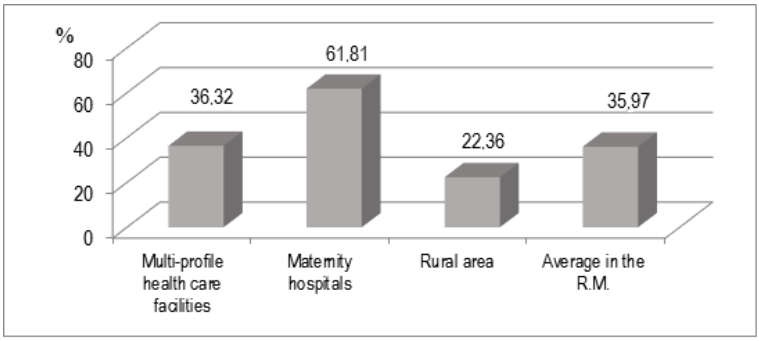

Fig. 1. Share of MRS strains in the total number of *Staphylococcus* strains isolated from patients with PSIs in the Republic of Moldova

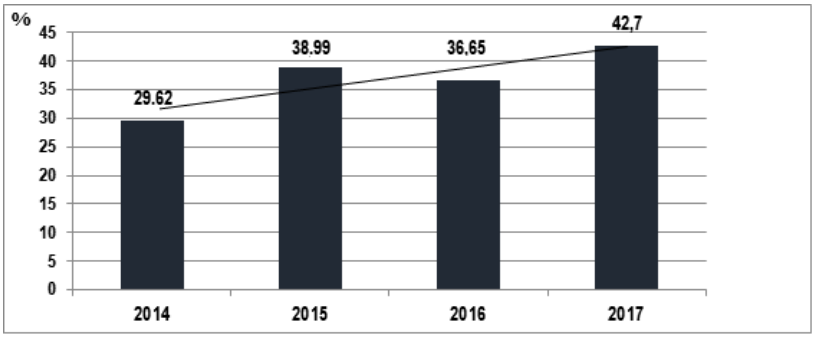

Fig. 2. Share of MRS strains in the total number of *Staphylococcus* strains in multiannual dynamics

Purulent-septic MRS infections are caused by both coagulase-positive staphylococci and coagulase-negative staphylococci. The analysis of the share of methicillin-resistant *Staphylococcus* strains depending on the staphylococcal species revealed different levels (fig. 3).

Of the total number of *S. aureus* strains tested for sensitivity / resistance to oxacillin, 19.43% showed to be resistant, while *S. hominis* strains were found to be resistant to oxacillin in 94, 44% of cases, *S. epider-*

midis - in 61.34%, *S. saprophyticus* - in 51.54%, and *S. hemolyticus* - in 48.71% (fig. 3). Although coagulase-positive *Staphylococcus* is more common in human purulent-septic infections, the degree of resistance to methicillin is lower compared to that of coagulase-negative *Staphylococcus* species (fig. 3).

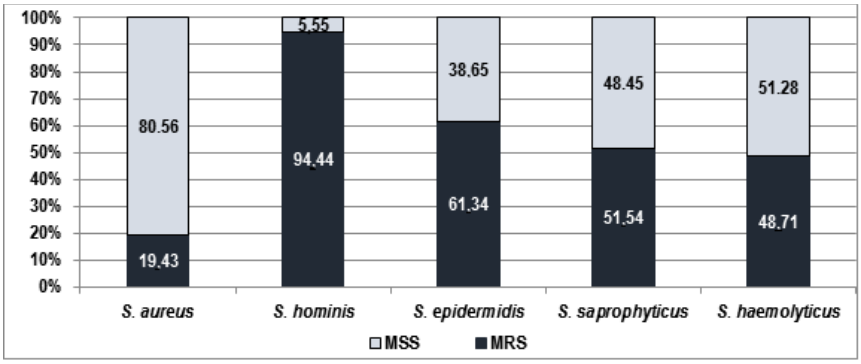

Fig. 3. Share of methicillin-resistant *Staphylococcus* strains by staphylococcal species

Staphylococcus strains showed varying resistance to methicillin, depending on the biological substrate investigated (tab. I). An obviously high share of MRS was found in blood cultures. Of the total number of *Staphylococcus* strains isolated from blood (n = 201), 76.11% (n = 153) of the strains were found to be methicillin resistant. The high share of MRS strains isolated from the blood allows to consider the given problem as a serious one, because it is a question of generalized infections (pneumonia, septicemia).

The isolation of MRS strains also varied depending on the profile of the inpatient department. A higher rate of MRS strains were isolated from patients with PSIs in the departments of surgery - 26.08%, traumatology and orthopedics - 19.84%, resuscitation and intensive care units - 15.20%. However, 14.84% of MRS strains were isolated from patients undergoing outpatient treatment.

A significant share of MRS infections was also found in the therapeutic departments: general therapy and allergology - 5.81%, hepatology - 3.86%, rheumatology/arthrology - 3.64%.

TABLE I

Share of methicillin-resistant *Staphylococcus* strains in various pathological products

Pathologic material	Total	Including MRS	
		N	%
Taken from the respiratory airways	1,230	205	16.66
Taken from the urogenital tract	510	117	22.94
Bile	326	158	48.46
Blood	201	153	76.11
Other bio substrates	837	257	30.70
Total	3,104	890	8.67

TABLE II

MRS/MSS strains resistance/sensitivity to non-β-lactam antibiotics, isolated from patients with septicemia

Antibiotic group	Type of antibiotic	Causative agent						Statistical difference
		MRS			MSS			
		Total	R		Total	R		
		n	n	%	n	n	%	
Aminoglycosides	Gentamicin	265	163	61.50	74	2	2.70	t=3.53, p<0.001

	Total	**1212**	**509**	**41.99**	**470**	**34**	**7.23**	t=7.02 p<0.001

MRS strains were also found to be resistant to non-β-lactam antibiotics. A fairly high resistance to antibiotics was found in MRS strains isolated from the blood (tab. II).

The resistance of MRS strains to macrolides accounted for 73.39%, including to erythromycin - 71.05% and clarithromycin - 73.86%. MSS strains showed much lower resistance values to this group of antibiotics - 26.08%, with a statistical difference t = 5.57, p<0.001 (clarithromycin –28.73% (t = 4.62, p <0.001), and erythromycin - 17.85% (t = 2.64, p<0.001)).

Differences in MRS and MSS strains resistance / sensitivity were also determined in the case of aminoglycosides, being 45.96% in the case of MRS strains, and only 2.02% in the case of MSS, (t = 7.06, p <0.001), including gentamicin - 61.50% (MRS) and 2.70% (MSS), (t = 3.53, p <0.001), tobramycin - 61.07 (MRS) and 2.47% (MSS), (t = 5.08, p <0.001), amikacin - 24.84 (MRS) and 2.02 (MSS), (t = 1.69 p <0.001).

MRS strains showed resistance to tetracyclines - 31.15%, compared to MSS strains - 1.69% (t = 2.13, p <0.05). MRS strains also showed high resistance to fluoroquinolones - 41.99%, compared to a much lower resistance of MSS strains - 7.23% (t = 7.02, p <0.001). MRS strains also showed resistance to ciprofloxacin - 43.13%, and MSS - 3.25% (t = 3.59, p <0.001), moxifloxacin - 30.31% and 17.18%, respectively (t = 1.38, p > 0.05), gatifloxacin - 67.55% and 5.37% (t = 5.57, p <0.001), levofloxacin - 31.54% and 2.38% (t = 2.48, p <0.05).

MRS strains isolated from the blood of patients with septicemia proved to be polyresistant in 96.3% of cases and sensitive to antibiotics in only 3.69%, while most strains of MSS - 91.66% proved to be sensitive to antibiotics, and only in 8.33% - polyresistant, the difference being statistically significant (t = 9.99, p <0.001).

TABLE III

Risk factors for PSIs caused by MRS strains

Risk factors	Research group (n=269)	Control group (n=159)	t-Student Test
Age ≥ 50 years	189 (70.26%)	95 (59.74%)	t = 1.74, p>0.050
Repeated hospitalization	176 (65.42%)	68 (42.76%)	t = 3.24, p<0.010
Microbial associations	158 (58.73%)	41 (25.78%)	t = 4.18, p<0.001
Exposure to intensive care	174 (64.68%)	56 (35.22%)	t = 4.01, p<0.001

Analysis of morbidity according to age groups (tab. III) shows that PSIs caused by MRS strains are more common in elderly patients (≥ 50 years) - 70.26%, compared to those with MSS - 59.74% (t = 1.74, p > 0.05). The character of repeated hospitalizations can be highlighted among the risk factors fPSIs caused by methicillin-resistant *Staphylococcus* strains. A higher incidence of patients exposed to repeated hospitalizations is observed in patients with MRS. Of the total number of patients, from whom MRS strains were isolated, 65.42% underwent repeated hospitalizations, and only 34.58% of them underwent the first hospitalization. In the control group, patients with MSS infections underwent the first hospitalization - 57.24% and only

42.76% - repeated hospitalization (t = 3.24, p <0.01).

Infections caused by MRS were found to have a higher proportion - 58.73%, being in combination with other species of microorganisms, compared to those caused by MSS strains - 25.78%, producing mostly (41.10%) generalized forms (pneumonia, septicemia, etc.). Another risk factor is exposure of patients to intensive care, 64.68% of patients with MRS infections being subjected to treatment in intensive care units, and only 35.22% of patients with MSS infections underwent treatment in the intensive care units (t = 4.01, p <0.001).

TABLE IV

Number of hospitalization days of patients with PSIs caused by MRS and MSS strains

Number of days	Indices	MRS		MSS	
		Number of patients	Total days	Number of patients	Total days
1-20	n	135	1,686	130	1,442
	%	63.38		86.09	
21-40	n	64	1,773	19	488
	%	30.04		12.58	
≥ 41	n	14	827	2	123
	%	6.57		1.32	
Total	n	213	4,286	151	2,053
Average hospitalization days		**20.12**		**13.59**	

Patients with PSIs caused by MRS strains had a much longer hospital stay, which averaged 20.12 days, compared with those with MSS - 13.59 days. Of the total number of patients with MRS, 6.57% followed treatment in the inpatient department for more than 41 days, compared to those with MSS - 1.32%. The lethality of patients with purulent-septic infections caused by MRS accounted for 21% (tab. IV).

DISCUSSION

Excessive and irrational use of antibiotics remains one of the main risk factors for increasing bacterial resistance to antibiotics. In the first report about antimicrobial resistance, WHO notes that it has become a major global threat to public health (4, 5).

Infections caused by antibiotic-resistant microorganisms, including MRS infections, significantly increase economic costs by extension of hospitalization, increasing the period of incapacity for work, increased use of antibiotics and other means and methods of diagnosis and treatment. Methicillin resistance was shown to have a negative impact on clinical and economic outcomes, especially in terms of increased morbidity and mortality, long-term hospitalization, as well as the need for additional interventions to reduce the clinical impact (13, 14).

Patients with MRS proved to have more comorbidities, more complications during hospitalization, requiring additional investigations, long-term hospitalizations, including intensive care, more complex and expensive treatment. Much higher costs for the treatment of MRS infections than for

MSS infections are due to both the higher number of treatment days and additional costs, which include costs for screening, use of personal protective equipment, and costs of antibiotics and drugs used in the treatment and decolonization of patients (15, 16). Patients with SPI caused by the MRS strains included in the current study had a much longer duration of hospitalization compared to those with MSS, the difference in average being 6.5 days.

Shortly after the appearance of MRSA, it has been realized that the problem of methicillin resistance involves not only coagulase-positive staphylococcal strains, but also coagulase-negative staphylococcal strains. Although in the beginning, these species of microorganisms were given little importance, being considered part of the normal flora of the skin and nasal mucosa, today because of resistance to antibacterial preparations have become a source of concern for the health system (17, 18). Our results demonstrated that in Republic of Moldova, although coagulase-positive *Staphylococcus* is frequently involved in septic-purulent human pathology, the degree of resistance to methicillin is lower (21.2%) compared to the same in staphylococcal species coagulase-negative (59.6%).

Given the continuous evolution of the phenomenon of antibiotic resistance, including methicillin-resistant *Staphylococcus*, it is important to establish the level of distribution and the degree of antibiotic sensitivity/resistance at both levels, namely, health care facilities and national level. Promoting global surveillance of antibiotic resistance through programs such as *ICARE*, *SENTRY*, *MYSTIC*, *EARSS*, also emphasizes the importance of implementing local studies or national surveillance programs to highlight circulating phenotypes in order to guide selective or empirical antibiotic therapy in clinical situations, thus requiring the initiation of an early antibacterial therapy (6, 19).

CONCLUSIONS

Methicillin-resistant *Staphylococcus* infections present a major public health problem both worldwide and in the Republic of Moldova. The degree of spread of methicillin-resistant *Staphylococcus* strains in the Republic of Moldova is on average 35.97% and varies depending on the type of health care setting: maternity hospitals - 61.81%, multi-profile health care facilities - 36.32%, health care facilities in rural areas - 22.36%. A very high resistance to methicillin is found in coagulase-negative *Staphylococcus* strains (48.71-94.44%). More frequently, MRS strains were isolated from patients in the inpatient departments of surgery, traumatology, orthopedics, and intensive care. MRS strains have a much higher resistance to non-beta-lactam antibiotics compared to MSS strains, and 96.3% of blood-isolated MRS strains have been shown to be polyresistant. People over 50 years, repeated hospitalizations, microbial associations, and exposure to intensive care have been shown to be risk factors for infections caused by MRS. In MRS infections, the medical, economic and moral impact is significant, the lethality being 21%. Rational and selective use of antibiotics based on antibiotic susceptibility test is the only chance to improve the situation.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received specific funding regarding this scientific research in the Project, code 20.80009.8007.05.

TOTAL HIP ARTHROPLASTY FOLLOWING OPEN REDUCTION AND INTERNAL FIXATION FOR DISPLACED ACETABULAR FRACTURES (Abstract): Fractures of the acetabulum are difficult to treat and even after fixation they can lead to posttraumatic arthritis and avascular necrosis of the femoral head. Total hip arthroplasty has been the most common surgery performed for the complications of posttraumatic arthritis and avascular necrosis of the femoral head. **Aim**: To evaluate the links between acetabular fracture type, radiological and clinical outcomes of open reduction and internal fixation, and clinical outcomes of total hip arthroplasty. **Material and methods:** One hundred thirty-two patients with acetabular fractures were treated surgically at the Trauma Department of "Sf. Spiridon" County Clinical Emergency Hospital from Iasi. Fifteen patients underwent THA for posttraumatic osteoarthritis or femoral head avascular necrosis following open reduction and internal fixation for acetabular fractures. Clinical and radiographic examinations were performed at 6 weeks, 3 months, 6 months, 1 year, and annually thereafter. Patients were assessed clinically using the Harris Hip Score and radiologically with Matta outcome grading. Heterotopic ossification was classified according to Brooker grading. **Results:** Mean Harris Hip Score has improved from 55 before conversion to 90 at 6 months after THA. No dislocation, deep vein thrombosis or pulmonary thromboembolism, new nerve injury, and heterotopic ossification occurred. **Conclusions:** The conversion to total hip arthroplasty after posttraumatic arthritis and avascular necrosis of the femoral head in acetabular fracture can lead to reasonable pain relief and functional improvement. **Keywords:** ACETABULAR FRACTURE, INTERNAL FIXATION, TOTAL HIP ARTHROPLASTY, POSTTRAUMATIC ARTHRITIS, AVASCULAR NECROSIS OF THE FEMORAL HEAD.

Acetabular fractures are serious intra-articular injuries which can lead in time to impairment of the hip joint function (1). Most frequently, these fractures emerge in young patients following high energy trauma, especially road accidents, in which the acetabular fracture is often associated with hip dislocation. The increase in life expectancy is associated with a higher number of elderly patients suffering fragility fractures. These are low energy fractures that affect the pelvic ring, but they can also be located at the acetabulum. The number of patients not receiving therapy for osteoporosis is

still high and the damaged bone structure causes delayed healing and recovery after pelvic fractures (2).

Most studies have shown that only the surgical treatment of these fractures, with anatomic reduction and rigid internal fixation, can restore the hip function and prevent long-term complications. Technological developments have made possible the routine surgical approach to acetabular fractures. The use of computed tomography (CT) in most traumatology services has allowed surgeons to better organize the stages of surgery (3). The three-dimensional printing technique allowed to obtain a model on which the reduction techniques can be planned and the plates to be used can be contoured preoperatively (4). Surgery duration is thus reduced. Unfortunately, despite modern fracture reduction techniques, 27% to 37% of the patients develop posttraumatic arthritis or avascular necrosis of the femoral head (AVN) (5, 6). Favoring factors for the development of these complication are early cartilage damage, residual articular incongruity, improperly placed implants, disruption of femoral head blood supply and associated comorbidities (7, 8).

The procedure indicated in case of any hip arthritis and/or femoral head necrosis is total hip arthroplasty (THA). Following acetabular fractures, this procedure is more complex due to the scar tissue, acetabular bone defects, and retained internal fixation implants (9, 10). The presence of osteosynthesis materials in the immediate vicinity of the acetabulum makes it sometimes necessary to partially remove it. These surgeries have a high degree of complexity and increased risks. Particular situations have also been described in the literature in which the acetabular fracture appeared in the context of a hip dislocation associated with ipsilateral trochanteric fracture, osteosynthesis implants being now present in the proximal femur (11).

Geriatric patients with acetabular fractures are currently being operated on. In the literature there are studies on the outcomes of surgeries including patients over 80 years of age. The complication rate is higher due to insufficient bone stock, and many patients require conversion to THA.

Additionally, another factor which needs to be considered when deciding for THA is that most patients with acetabular fractures are young, with high activity level, and subsequent high failure rates of THA (12, 13, 14).

The aim of the study was to evaluate the links between acetabular fracture type, radiological and clinical outcomes of open reduction and internal fixation (ORIF), and clinical outcomes of THA.

MATERIAL AND METHODS

Patient data. From July 1, 2011, to December 31, 2019, 132 patients with acetabular fractures were treated surgically, ORIF, at the Trauma Department of the University Hospital, Iasi, Romania, by the same senior surgeon. Out of these, fifteen patients underwent THA. Informed consent was obtained from all the individual participants included in the study. The study was conducted according to the Helsinki Declaration and was approved by the Ethics Committee of the 'Sf. Spiridon' Emergency Hospital Iasi, Romania.

Inclusion criteria were patients > 18 years of age, diagnosis of posttraumatic osteoarthritis or femoral head avascular necrosis following ORIF for acetabular fractures, patients suitable for surgical treatment and a minimum follow-up of 1 year after THR.

After identifying the patients, we retro-

spectively reviewed the demographic data, type of fracture according to Letournel classification (15, 16), mechanism of trauma, initial treatment of the fracture, time between fracture treatment and THR, type of prostheses, complications, follow-up time.

Surgical Technique. All THAs were performed through a modified Hardinge approach. The acetabulum was prepared for routine primary THA. Hardware from ORIF was not routinely removed. Heterotopic ossifications (HO) were removed only if they interfered with the reaming and placement of the cup/acetabular reinforcement ring. Acetabular bone defects were assessed based on the American Academy of Orthopedic Surgeons (AAOS) classification (17). In large bone deficiency, for acetabular reconstruction we used a cemented acetabular fixation combined with an acetabular reinforcement ring and morselized cancellous bone grafts from the resected femoral head. Cementless acetabular fixation was used in cases without large bone defects using press-fit technique, and/or additional screw fixation. All femoral stems were cementless. Joint articulation was either ceramic-on-cross-linked polyethylene or ceramic-on-ceramic.

Perioperative protocol. Antibiotic prophylaxis was started 30 minutes before the incision in the operating room and within the first 24 hrs. postoperatively. To prevent thromboembolism, low molecular weight heparin was routinely administered for one month. Prophylaxis against HO consisted in the administration of indomethacin 75 mg daily for 21 days. All patients were allowed to do passive movements following surgery and were restricted to touch-down weight-bearing walking for 6 weeks and gradually increase this to full weight-bearing thereafter.

Clinical and radiological assessment. Postoperative follow-up was performed at 6 weeks, 3 months, 6 months, 1 year and annually thereafter. Patients were assessed clinically using the Harris Hip Score (HHS) (18) and radiologically with Matta outcome grading (19). HO was classified according to the system developed by Brooker *et al.* (20)

Statistical analysis. The database was created in EXCEL and was statistically processed with the *SPSS version 18.0* software (IBM, Armonk, New York, USA).

RESULTS

All acetabular fractures were caused by high-energy trauma (motor vehicle accidents, falls from height) and were treated primarily with open reduction and internal fixation after fracture reduction. Most patients had complex fractures and were all first treated with plates and screws.

The mean patients age of 42±11.25 years (range from 22 to 78 years). Ten patients (66.6%) were men and 5 were women (male/female=2/1). Among the fifteen patients who underwent THR, left side was affected in 9 cases (tab. I).

Three patients had isolated posterior wall fractures and 12 patients had complex fractures (when >2 simple fractures were combined): transverse and posterior wall fractures were found in 9 patients, posterior wall and posterior column fractures in one, T-shaped fracture, and anterior column and posterior hemi transverse fracture in one patient each. Posterosuperior dislocation was found in 7 patients and central dislocation in 3 patients. For the posterior wall fracture component Kocher - Langenbeck approach and for all other fractures the modified Stoppa approach or combined anterior and posterior approaches were used (3, 21, 22).

TABLE I
Demographic data of the study group

Variables	Values
Mean age (years)	42±11.25
Gender	
Male/Female	10/5
Mean body mass index (kg/m^2)	26.2±9.31
Preoperative diagnosis	
Posttraumatic osteoarthritis	9 (60)
Femoral head necrosis	6 (40)
Fracture patterns	
Posterior wall	3 (20)
Posterior wall + posterior column	1 (6.6)
Transverse + posterior wall	9 (60)
T-shaped	1 (6.6)
Anterior column + posterior hemi transverse	1 (6.6)
Dislocation	
Posterosuperior	7 (46.6)
Central	3 (20)
Interval time between fracture ORIF and THA (months)	18±16.33
Median follow-up (months)	12±8.41

Values are expressed as mean ± SD, frequency and percentage (%)
ORIF=open reduction and internal fixation, THA=total hip arthroplasty

After ORIF for acetabular fractures, patients were assessed radiologically using Matta outcome grading. Here the patients are divided into three groups: anatomical, congruent and incongruent group. Based on this division 9 outcomes were in anatomical group and 6 outcomes in congruent group. Functional outcomes were divided into four groups according to HHS: poor, fair, good and excellent. Thus, 9 outcomes were excellent, 3 good and 2 fair. HO was observed in 4 patients. Posttraumatic sciatic nerve palsy was recorded in 3 cases.

The most common cause for THA was posttraumatic osteoarthritis (9 patients) followed by femoral head necrosis (6 patients). THA was performed after an average of 18±16.33 months after acetabular fracture ORIF (range from 7 to 30 months).

During THR we found protrusion of the hardware into the acetabulum (a screw in one case, bone necrosis of the posterior wall fragment with subsequent posterior plate and/or spring plates in other 7 cases). In these cases, protruded hardware needed to be removed prior to THA (fig. 1).

Cementless cup was used in 7 cases, in others (due to large bone defects) cemented cup combined with an acetabular reinforcement ring and morselized cancellous bone grafts from the resected femoral head were use. All the femoral stems were uncemented (fig. 2).

As for postoperative complications, we recorded one case of superficial infection treated with debridement and vacuum-assisted closure (23) and in another case increased of HO from Brooker 2 to Brooker 3 at 6 months follow-up without clinical impairment.

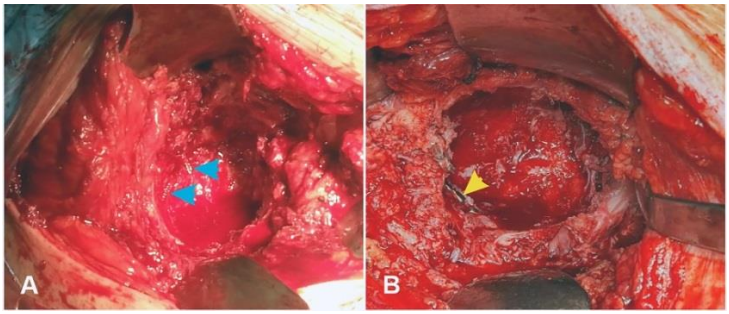

Fig. 1. Intraoperative imagines during THA, intraacetabular view: **A** - protrusion of screws into the acetabulum (blue arrows), **B** - posterior wall fragment necrosis with subsequent protrusion of the posterior reconstruction plate into the acetabulum (yellow arrow).

Fig. 2. Example of transverse + posterior wall fracture (29-year-old female): preoperative 3D CT scan (**A, B**); ORIF for acetabular fracture: postoperative X-rays (**C** - antero-posterior, **D** - iliac oblique and **E** - obturator oblique views) - internal fixation with omega plate throughout anterior (modified Stoppa) approach of the transverse component and additional fixation with a reconstruction plate and two spring-plates throughout posterior (Kocher-Langenbeck) approach of the posterior wall fragments, postoperative CT scan (**F** - axial, **G** - coronal, **H** - sagittal) - articular congruence with anatomical reduction of the acetabular surface (Matta 1), 15-monhts follow-up (**I** - anteroposterior X-ray view and **J** - coronal CT scan) - avascular necrosis of the femoral head (Ficat and Arlet stage IV); THR: postoperative X-ray (K - anteroposterior view) - uncemented THR, fracture fixation hardware was kept in place except the two spring plates because the plate hooks protruded into the acetabulum, 6-months follow-up (**L** - anteroposterior X-ray view).

The HHS was used to evaluate the outcomes of the conversion procedure (THR) with regard to pain alleviation and functional improvement at 12 months, even though the HHS at the final follow up was documented for all patients. Based on the outcomes, HHS improved from an average of 55 before THA to an average of 90 at 12 months after THA.

DISCUSSION

Posttraumatic osteoarthritis and femoral head necrosis may occur in patients with acetabular fracture treated with open reduction and internal fixation. Although the complications are quite numerous and require complex solutions, the surgical treatment of displaced fractures is clearly superior to the conservative one where the complication rate is much higher (21, 22). It is predictable that surgical treatment will become the first option even in people at extreme old age, the advantages being shown by studies on the postoperative survival rate of patients who have suffered hip fractures (24).

Out of the factors that affect the outcome of acetabular fractures surgery, in our study the surgeon-dependent variables could be excluded because all the fractures were treated by the same surgeon. The surgeon-independent variables are: the mechanism of the injury, damage to the femoral head, sciatic nerve injury, dislocation, fracture pattern, associated injuries, the patient's age and comorbidities. The external examination of the patient is thus important and identifying associated injuries can significantly impact treatment outcome (25). The implication of the age and gender could not be substantiated because the patients in our group are young or in the middle age (the mean patient age was 42±11.25 years). The hip dislocation is another variable that is known to negatively affect the outcome (26). Related to fracture pattern, most published studies reported poorer outcome in posterior wall, posterior column, posterior wall + posterior column and T fractures due to cartilage damage, impaction and comminution (26, 27, 28, 29). It was suggested that primary THR of these fractures is a better option, but large randomized clinical trials are needed to validate available data (30). From our patients that underwent THR, in 10 cases (66.6%) the acetabular fracture was associated with dislocation. Posterior wall/column fracture component was encountered in 13 patients (86.6%) and T-shape fracture in one patient. All of our patients but one (78-years old female) were treated primarily with ORIF of the acetabular fracture.

THA, although considered a reliable procedure, has a higher incidence of complications and poorer outcomes than non-traumatic primary THA (31, 32). Cemented THA following acetabular fractures was preferred in earlier studies, however, later studies showed increased revision and loosening rates in the acetabular side. Authors suggested that a sclerotic bone bed in the acetabulum is inappropriate for cement fixation (33, 34). Improved outcomes of cementless THA after acetabular fractures have been reported. These studies suggested that the improved outcomes were due to the development of cementless acetabular fixation in THA and fracture management (31, 32).

In our study we recorded good clinical, radiological and patient-related outcomes, without the presence of serious complications after the surgical treatment of acetabular fracture or THA and no differences

between cemented and uncemented THA.

CONCLUSIONS

The findings of the present study suggest that the THA of posttraumatic arthritis or femoral head necrosis after acetabular internal fixation is clinically successful without increased risk of complications and provides good functional results.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

VERBASCUM NIGRUM L. AND *AJUGA CHIA* SCHREB.: ANTIOXIDANT ACTIVITY AND CORRELATION WITH PHENOLIC CONTENT (Abstract): **Aim**: The aim of the present study was to investigate the antioxidant potential of *Verbascum nigrum* L. and *Ajuga chia* Schreb. aerial parts in correlation with their phenolic contents. **Material and methods**: Each plant material was subjected to a five-step sequential extraction procedure using diethyl ether, dichloromethane, ethyl acetate, methanol and water. The total phenolic content was determined using the Folin-Ciocalteu method. Antioxidant activity was assessed using six *in vitro* assays: DPPH radical, ABTS radical cation, superoxide anion radical and hydroxyl radical scavenging assays, reducing power and ferrous ions chelating assay. **Results and discussion**: The highest phenolic contents were found in *Verbascum nigrum* ethyl acetate and methanol extracts (199.35 ± 3.63 and 181.94 ± 2.38 mg/g, respectively). *Verbascum nigrum* methanol extract developed the most potent scavenging effects against DPPH, ABTS and superoxide radicals and showed the strongest reducing power (EC_{50} = 28.03 ± 0.40, 17.77 ± 0.00, 990.00 ± 0.01 and 17.30 ± 0.12 µg/mL, respectively). *Verbascum nigrum* aqueous extract strongly chelated the prooxidant ferrous ions (EC_{50} = 0.05 ± 0.01 mg/mL). There were found strong positive correlations between the antioxidant activity (DPPH and ABTS scavenging activity, reducing capacity) and phenolic content of *Verbascum nigrum* extracts. **Conclusions**: *Verbascum nigrum* is a rich source of antioxidant compounds and needs further investigations on the metabolite profiling and bioactivity. **Keywords**: *VERBASCUM NIGRUM*, *AJUGA CHIA*, ANTIOXIDANT ACTIVITY.

Oxidative stress, a state in which a biological system becomes unable to neutralize the highly reactive oxygen species, is involved in the initiation and progression of various diseases (malignant, inflammatory, metabolic and autoimmune diseases) (1). *Verbascum* genus belongs to the Scrophulariaceae family, the latter including more than 2,500 species (mulleins) distributed around the world. Mulleins have various uses in the traditional medicine, with reported expectorant, emollient, antiseptic, antimalarial, antiulcerogenic, hepatoprotective and cytotoxic properties (2). Chemical studies have revealed the presence of flavonoids, iridoids, saponins and phenylethanoids as

main classes of bioactive compounds in *Verbascum* species (3). *Ajuga* (Lamiaceae family) is a genus including around 300 species (4). Sterols, iridoids, withanolides, polyphenols, polyketides and alkaloids, as well as essential oils (4-7) confer various activities (antimicrobial, antimalarial, anti-inflammatory, hypoglycemic, antioxidant, wound healing, neuroprotective) to *Ajuga* extracts (4, 8-12).

Although *Verbascum* and *Ajuga* species have been thoroughly investigated, there is scarce information about the chemical composition and bioactivity of *Verbascum nigrum* L. (black mullein, dark mullein) and *Ajuga chia* Schreb. (syn. *Ajuga chamaepitys* subsp. *chia* (Schreb.) Arcang., yellow bugle, ground-pine). In this respect, the present study evaluated the antioxidant potential of the aforementioned species in correlation with their phenolic contents.

MATERIAL AND METHODS

Plant material: The aerial parts of *V. nigrum* and *A. chia* were collected in the Republic of Moldova (Merenii Noi and Hlinaia, respectively) in May 2014. The aerial parts were dried, powdered and deposited in the Department of Pharmacognosy, Faculty of Pharmacy, *Grigore T. Popa* University of Medicine and Pharmacy Iasi, Romania.

Extraction: The dried and powdered aerial parts of *V. nigrum* and *A. chia* (20 g each) were extracted by a five-step sequential extraction procedure, using solvents with increasing polarities (diethyl ether, dichloromethane, ethyl acetate, methanol and water, 3 × 200 mL, 1 h) at room temperature. The resulting extracts were concentrated in a rotary vacuum evaporator at 40-45°C, freeze-dried and kept at -20°C until further use.

Total phenolic content: Total phenolic content was assessed using the Folin-Ciocalteu method, the results being expressed as gallic acid equivalents (mg gallic acid/g extract) (13, 14).

Antioxidant assays: The scavenging capacity against synthetic free radicals (1,1-diphenyl-2-picrylhydrazyl (DPPH) radical, 2,2'-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) radical cation) and reactive oxygen species (superoxide anion radical, hydroxyl radical), reducing power and capacity to chelate the prooxidant ferrous ions were evaluated using previously described methods with minor changes (15-22).

Statistical analysis: The results are expressed as means ± standard error mean (SEM) of three replicates. *Microsoft Home and Business 2019* was used for the statistical analysis.

RESULTS

Total phenolic content: The phenolic content of *V. nigrum* extracts ranged from 0.25 ± 0.01 mg/g (VN5) to 199.35 ± 3.65 mg/g (VN3), VN4 and VN3 extracts showing the highest phenolic amounts. In case of *A. chia* extracts, the phenolic content varied between 35.07 ± 0.70 mg/g in AC1 to 90.55 ± 2.29 mg/g in AC5 (tab. I).

DPPH radical scavenging activity: At 84 µg/mL, two of *V. nigrum* extracts, VN3 and VN4, exhibited significant and similar scavenging effects (86.80 ± 0.02% and 85.53 ± 0.01%, respectively). At the same concentration, VN1, VN2 and VN5 extracts showed weak activity (7.35 ± 0.12%, 10.55 ± 0.25% and 6.55 ± 0.23%, respectively). At the highest concentration tested (333 µg/mL), VN3 and VN4 extracts scavenged 98% of the DPPH free radical. With respect to *A. chia* extracts, AC5 was the most active,

with 82.26 ± 3.00% scavenging activity at 333 µg/mL. According to the EC_{50} values (tab. II), VN3 and VN4 extracts proved to be efficient DPPH radical scavengers.

TABLE I

Extracts obtained by five-step sequential extraction of *Verbascum nigrum* and *Ajuga chia* aerial parts and their phenolic contents

Extraction solvent	*V. nigrum* aerial parts			*A. chia* aerial parts		
	Extract	Amount (g)	Total phenolic content (mg/g)	Extract	Amount (g)	Total phenolic content (mg/g)
Diethyl ether	VN1	0.35	26.70 ± 1.59	AC1	0.15	35.07 ± 0.70
Dichloromethane	VN2	0.17	50.77 ± 1.54	AC2	0.22	38.36 ± 1.82
Ethyl acetate	VN3	0.60	199.35 ± 3.63	AC3	0.20	38.71 ± 0.72
Methanol	VN4	5.72	181.94 ± 2.38	AC4	3.42	50.85 ± 1.11
Water	VN5	3.06	0.25 ± 0.01	AC5	3.23	90.55 ± 2.29

ABTS radical cation scavenging activity: At 50 µg/mL, VN3 and VN4 extracts exhibited 100% ABTS scavenging activity. At the same concentration, VN2 and VN5 extracts developed two-fold weaker scavenging effects (52.59 ± 0.02% and 56.45 ± 5.82%, respectively). VN1 extract was almost inactive, showing only 9.52 ± 0.02% scavenging activity at 100 µg/mL. According to the EC_{50} values, none of the *V. nigrum* extracts reached the scavenging potency of the positive controls, catechin and quercetin (tab. II). *A. chia* extracts showed weak scavenging activity. At 300 µg/mL, AC2 and AC3 extracts scavenged the ABTS radical cation by only 23.00 ± 1.83% and 21.97 ± 3.56%, respectively, whereas AC4 and AC5 extracts showed slightly higher scavenging activities (35.10 ± 5.54% and 33.22 ± 8.49%, respectively).

Reducing power: VN3 and VN4 extracts were the most active, with 100% reducing activity at 60.6 µg/mL. VN2 and VN5 extracts showed weaker effects (58.51 ± 0.14% at 182 µg/mL and 66.81 ± 4.42% at 121 µg/mL, respectively). No activity was observed for VN1. With respect to the EC_{50} values, catechin showed the strongest reducing potential (6.50 ± 0.11 µg/mL), followed by VN3 and VN4 extracts, with comparable EC_{50} values (18.22 ± 0.32 and 17.30 ± 0.12 µg/mL, respectively). Among *A. chia* extracts, AC4 and AC5 were the most potent (39.84 ± 1.44 and 92.31 ± 6.29 µg/mL, respectively) (tab. II).

Ferrous ion chelating activity: Except VN3, all other four *V. nigrum* extracts exhibited dose-dependent ferrous ion chelating effects. At 2 mg/mL, VN2 was the most potent (97.63 ± 0.01%), followed by VN4 (94.06 ± 0.00%) and VN1 (76.72 ± 0.00%). However, according to the EC_{50} values, the strongest chelating activity was exhibited by VN5 extract (0.05 ± 0.01 mg/mL) (tab. II). With respect to *A. chia* extracts, AC2, AC4 and AC5 exhibited strong chelating effects at 2 mg/mL: 99.29 ± 0.00%, 97.80 ± 0.01% and 96.54 ± 0.01%, respectively. According to the EC_{50} values, the ferrous ion chelating ability of *A. chia* extracts varied in the following order: AC5 > AC3 > AC2 > AC4 > AC1 (tab. II).

Superoxide anion radical scavenging activity: Within 1-3 mg/mL concentration range, *A. chia* extracts showed mild super-

oxide anion radical scavenging effects, with the highest activity for AC2 (30.70 ± 0.02% at 3 mg/mL). Among *V. nigrum* extracts, VN4 was the most active (EC_{50} = 990 µg/mL), but significantly less active than the positive control, glutathione (EC_{50} = 1.09 ± 0.01 µg/mL) (tab. II).

Hydroxyl radical scavenging activity: VN3 was the most potent *V. nigrum* extract, showing 93.36 ± 1.11% scavenging activity at 1.87 mg/mL and an EC_{50} value of 1.10 ± 0.03 mg/mL (tab. II). At the same concentration, VN4 and VN5 extracts had moderate activity (67.18 ± 3.87% and 54.13 ± 1.36%, respectively). VN1 and VN2 extracts exhibited weak scavenging effects (below 30%). According to the EC_{50} values, quercetin (0.16 ±0.01 mg/mL) was 6.8 times more potent than VN3 (tab. II). *A. chia* aqueous extract (AC5) scavenging activity varied from 5.96 ± 1.90% to 69.66 ± 1.91% within 0.23–0.94 mg/mL concentration range (EC_{50} = 1.24 ± 0.04 mg/mL) (tab. II). All other *A. chia* extracts showed weak effects (maximal inhibition below 30%).

TABLE II

Antioxidant activities of *Verbascum nigrum* and *Ajuga chia* aerial part extracts

ND – not determined (weak activity); NT – not tested; Q – quercetin; Cat – catechin;
GSH – reduced glutathione; EDTA-Na_2 - ethylenediaminetetraacetic acid disodium salt; *µg/mL.

DISCUSSION

The present study reports on the antioxidant potential of different extracts prepared from the aerial parts of *V. nigrum* and *A. chia* in relation to their phenolic contents. The highest amounts of phenolics (199.35 ± 3.65 and 181.94 ± 2.38 mg/g) were determined in *V. nigrum* ethyl acetate (VN3) and

methanol (VN4) extracts, respectively. According to literature data, in other *Verbascum* species extracts, the phenolic contents ranged from 39.47 ± 1.68 mg/g (*V. densiflorum*) to 51.94 ± 2.30 mg/g (*V. sinuatum*) (23), being significantly lower than those determined in VN3 and VN4 extracts. In *V. blattaria* ethyl acetate extract, the phenolic content was 4.5-fold lower (18) compared to *V. nigrum* ethyl acetate extract (VN3). A low phenolic content (28.70 ± 0.9 mg/g) was determined in *V. betonicifolium* mucilage free water extract (24). The phenolic content in *A. chia* methanol extract VN4 (50.85 ± 1.11 mg/g) was comparable to or higher than those reported in other *Ajuga* species methanol extracts (56.76 ± 0.92, 22.63 ± 0.61, 20.86 ± 0.53 and 5.94 ± 1.98 mg/g in *A. laxmanii, A. genevensis*, *A. reptans* and *A. bracteosa*, respectively) (15, 25, 26).

The antioxidant potential of *V. nigrum* and *A. chia* extracts was assessed by six *in vitro* assays. In brief, different mechanisms involved in the antioxidant activity, such as hydrogen donation, electron transfer and transition metal ions chelation were investigated.

Previous studies on the DPPH scavenging activity of other *Verbascum* species extracts reported various results: *V. antiochium* methanol extract and *V. blattaria* ethyl acetate extract had weak effects (EC_{50} values of 4.80 mg/mL and 667 µg/mL, respectively) (18, 27), whereas *V. speciosum, V. songaricum, V. cheirantifolium, V. thapsus, V. densiflorum* and *V. sinuatum* ethyl acetate extracts (EC_{50} values ranging from 9.81 ± 0.71 to 23.56 ± 0.94 µg/mL) (23) were more active as DPPH scavengers than *V. nigrum* ethyl acetate extract VN3 (EC_{50} = 35.84 ± 0.84 µg/mL). Mihailović *et al.* reported EC_{50} values varying from 60.7 ± 1.7 to 121.5 ± 2.9 µg/mL for *V. nigrum* (collected in Serbia), *V. phlomoides* and *V. thapsus* methanol extracts and higher ones (EC_{50} = 105.7 ± 1.9 - 257.0 ± 4.6 µg/mL) for the aqueous extracts obtained from the same species (28). *V. pseudoholotrichum* methanol and aqueous extracts were less active against DPPH radical than *V. nigrum* extracts VN4 and VN5 (EC_{50} = 775 *vs.* 28.03 µg/mL and EC_{50} = 539 *vs.* 312.32 µg/mL, respectively) (29). Similarly, *V. ovalifolium* methanol extract (EC_{50} = 40.97 ± 0.54 µg/mL) (30) was less active than VN4 extract. In contrast to the present study, good DPPH scavenging abilities were found for *A. genevensis, A. reptans, A. laxmanii* and *A. bracteosa* methanol extracts, with EC_{50} values of 72.08 ± 6.02, 83.16 ± 5.21, 24.89 ± 0.83 and 36.90 µg/mL, respectively (15, 25, 26).

With respect to ABTS radical cation scavenging capacity, the methanol extract VN4 (EC_{50} = 17.77 ± 0.00 µg/mL) was more active than the methanol extracts obtained from *V. nigrum* collected in Serbia (EC_{50} = 90.0 ± 1.6 µg/mL) and other *Verbascum* species (EC_{50} values of 121.4 ± 2.1 and 114.4 ± 2.6 µg/mL for *V. phlomoides* and *V. thapsus* methanol extracts, respectively) (28). Other studies on the antioxidant activity of *Ajuga* species expressed the ABTS scavenging activity as trolox equivalents and therefore, a comparison with our results is not feasible. However, the antioxidant activity varied among *Ajuga* species (30.38, 66.13 ± 2.87 and 60.98 ± 1.52 mg trolox equivalents/g extract for *A. orientalis*, *A. genevensis* and *A. reptans* methanol extracts, respectively) (26, 31).

The present study found high reducing power values for the ethyl acetate and methanol extracts of *V. nigrum* aerial parts, namely VN3 and VN4 extracts (EC_{50} = 18.22 ± 0.32 and 17.30 ± 0.12 µg/mL, respectively). Luca *et al.* reported good reducing capacities for *V. ovalifolium* ethyl

acetate and methanol extracts (EC_{50} = 15.19 ± 0.37 and 22.56 ± 1.04 µg/mL, respectively) (30). On the other hand, *V. ovalifolium* aqueous extract had lower reducing power than VN5 extract (EC_{50} = 114.56 ± 2.59 *vs.* 86.90 ± 4.37 µg/mL) (30). *V. atlanticum* ethyl acetate extract was slightly less active than VN3 (EC_{50} = 23.81 ± 0.16 *vs.* 18.22 ± 0.32 µg/mL) (32). Reducing properties were also reported for various *Ajuga* species. *A. bracteosa* methanol extract exhibited a reducing activity of 718.4 ± 36 mg ascorbic acid equivalent/g at 1 mg/mL (15).

Ferrous ions can generate reactive radicals, including the hydroxyl radicals and therefore, ferrous ions chelation reduces the oxidative stress (33). According to Mihailović *et al.*, methanol extracts of *V. sinuatum*, *V. nudicaule* and *V. speciosum* showed ferrous ion chelating abilities of 14.44 ± 4.89%, 19.06 ± 8.80% and 5.42 ± 0.72%, respectively, at a concentration of 1 mg/mL (28). Within 25–200 µg/mL concentration range, *A. iva* extracts had moderate metal chelating effects, with the methanol extract being the most active, followed by the aqueous and chloroform extracts (34). *A. chamaecistus* aqueous extract was reported to have a ferrous ion chelating potential equivalent to 5.25 ± 0.21 mg ethylenediaminetetraacetic acid equivalents/g (10).

Among all investigated extracts, only VN4 extract exhibited a weak scavenging activity against superoxide anion radical (EC_{50} = 990 µg/mL). Luca *et al.* found superoxide scavenging abilities for *V. ovalifolium* ethyl acetate, methanol and aqueous extracts (EC_{50} = 527.26 ± 2.00, 573.31 ± 2.05 and 2417.43 ± 39.93 µg/mL, respectively) (30). According to El Gizawy et *al.*, *V. nubicum* methanol extract had a weak superoxide scavenging potential (only 40% scavenging capacity at 0.8 mg/mL) (35). *A. chia* extracts obtained in the present study showed no superoxide scavenging activity within 1.0 - 3.0 mg/mL concentration range. AC2 extract was the most active (30.70 ± 0.02% scavenging activity at 3 mg/mL). To the best of our knowledge, literature data on superoxide scavenging activity of other *Ajuga* species is lacking.

Hydroxyl radicals, highly reactive species generated by Fenton reaction, are responsible for DNA oxidative damage and other deleterious effects (oxidative damage of lipids and aminoacids, protein unfolding) (36). The hydroxyl radical scavenging effects of *V. nigrum* extracts obtained in the present study are weaker than those reported in literature for extracts obtained from other *Verbascum* species (EC_{50} values of 6.0 ± 0.6 and 166.5 ± 3.6 µg/mL for *V. phlomoides* methanol and aqueous extracts, respectively; EC_{50} values of 9.8 ± 0.8 and 171.6 ± 5.0 µg/mL for *V. thapsus* methanol and aqueous extracts, respectively) (28). Literature data on the hydroxyl radical scavenging capacity of *Ajuga* species is limited. A methanol: chloroform leaf extract of *A. bracteosa* (grown *in vitro*) scavenged the hydroxyl radical with an EC_{50} value of 122.5 ± 0.9 µg/mL (37).

The correlation between the antioxidant activity of *V. nigrum* and *A. chia* extracts and their phenolic contents was evaluated using the Pearson's test (tab. III, fig. 1). There were found strong positive correlations between the antioxidant activity (DPPH and ABTS scavenging activity, reducing capacity) and phenolic content of *V. nigrum* extracts. There was no correlation between the antioxidant activity of *A. chia* extracts and their phenolic contents. The negative correlations between the ferrous ion chelating capacity of *V. nigrum* and *A. chia* extracts and their phenolic contents suggest that other compounds than phenolics are responsible for chelation ability.

TABLE III

Pearson's correlation coefficients (r) between the antioxidant activities of *Verbascum nigrum* and *Ajuga chia* extracts and their phenolic contents

	DPPH radical scavenging activity	ABTS radical cation scavenging activity	Reducing power	Ferrous ion chelating activity	Superoxide anion radical scavenging activity	Hydroxyl radical scavenging activity
***Verbascum nigrum* extracts TPC**	0.9522**	0.9175*	0.9532*	-0.5100	-	0.8872
***Ajuga chia* extracts TPC**	-	-	-	-0.5400	-	-

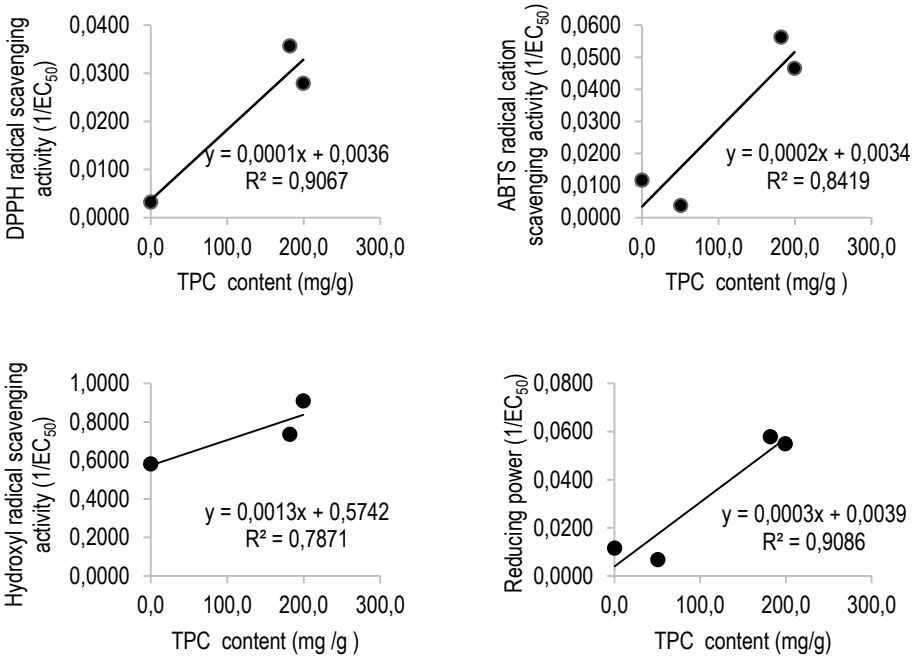

Fig. 1. Correlation between the antioxidant activity of *Verbascum nigrum* extracts and their phenolic contents

CONCLUSIONS

The current research evaluated the antioxidant potential and possible correlation with the phenolic content of ten extracts obtained from the aerial parts of *Verbascum nigrum* and *Ajuga chia* using five different polarity solvents. The assays revealed that *Verbascum nigrum* extracts had stronger antioxidant effects in comparison with *Ajuga chia* extracts. *Verbascum nigrum* ethyl

acetate and methanol extracts were efficient radical scavengers and reducing agents, with methanol extract being the most active in DPPH, ABTS and superoxide radicals scavenging assays, but also in the reducing power assay. On the other hand, *Verbascum nigrum* aqueous extract was the strongest ferrous ion chelator. Strong positive correlations were found between the antioxidant activity (DPPH and ABTS scavenging activity, reducing capacity) and phenolic content of *Verbascum nigrum* extracts. To conclude, *Verbascum nigrum* is a rich source of antioxidant compounds and needs further investigations on the metabolite profiling and bioactivity.

CONFLICT OF INTEREST AND FUNDING

Authors declare that there is no conflict of interest, and they received no funding for this study.

DESIGN AND OPTIMIZATION METHOD FOR OBTAINING NEW CHITOSAN-BASED NANOFIBERS FOR WOUND HEALING APPLICATIONS (Abstract): **Aim**: The aim of the present study was to establish the optimal parameters for obtaining electrospun nanofibers (NFs), in correlation with their nanometer size range. **Material and methods**: Several types of nanofibers were designed: CS_PEO@P, CS_PEO@M_L_P, CS_PEO@P_C, CS_PEO@I_P, which have incorporated different active components (ACs), such as propolis (P), Manuka honey (M), *Calendula officinalis* infusion (C), L-arginine (L) and insulin (I) into a chitosan-polyethylene oxide (CS_PEO) matrix. The nanofibers were obtained *via* electrospinning method, the optimal electrospinning parameters were established, the average diameter was determined with Fiber metric software and the morphology was assayed using SEM microscopy. **Results and discussion**: Only homogenous, randomly-oriented and continuous NFs were considered proper for the study. Furthermore, after determining the average diameter of the fibers, a value of 600 nm was considered a reference maximum. By incorporating ACs, the morphology and the average diameter of NFs changed, with the most notable difference in the case of CS_PEO@M_L, when an increase from 164 ± 17 nm (CS_PEO matrix) to 201 ± 6 nm (CS_PEO@M_L_P) was noted. **Conclusions**: Although the Manuka honey-based NFs have displayed a larger diameter, they presented a smoother morphology and homogenous distribution, which means that this type of NFs could be proper for biomedical applications. **Keywords**: CHITOSAN, NANOFIBERS, WOUND HEALING, ELECTROSPINNING.

Developing new options for the management of wound care is a major focus in the biomedical field, as there is an ever-growing need to improve wound healing materials while minimizing processing costs (1). This, in turn, gives the patient a better and more efficient possibility to adjust the therapy according to the healing

stage. If a wound fails to heal within three months, the wound becomes chronic, and complications are more likely to occur (2). This may be due to an impairment caused by the oxidative stress (under the form of reactive oxygen species: superoxide, hydrogen peroxide, and even hydrochloric acid) in the inflammatory phase, at the wound site (3). Furthermore, other factors such as diabetes (insulin deficiency) may affect the lipid, protein or carbohydrate metabolism, respectively, thus delaying the wound healing (4). The natural extracellular matrix (ECM) consists of fibrous proteins with diameters between 50 nm and 150 nm. Novel nanomaterials such as electrospun nanofibers (NFs) provide a proper matrix for wound healing (5), demonstrating beneficial effects regarding tissue formation (6). NFs are highly porous systems with a large surface which are obtained using electrospinning method. By acting as artificial ECM they promote cellular adhesion, proliferation, and differentiation. NFs can be designed and their properties could be adjusted, according to the features of polymer matrix and of the active compounds included to the matrix (7). Chitosan (CS) is a biodegradable polysaccharide, derivative of chitin, with a wide range of biomedical applications, based on its properties, such as polycationic structure, nontoxicity, biodegradability, mucoadhesive, antibacterial and antifungal effects (8). It consists of *β*-(1,4)-D-glucosamine and N-acetyl-D-glucosamine units and the glucosamine unit content depends on the degree of deacetylation (9). Polyethylene oxide (PEO) is often used as a copolymer to aid the electrospinning technique and facilitate the NFs obtaining process (10).

Having the polymer matrix consisting of CS and PEO (CS_PEO), the following active components (ACs) were chosen to be incorporated into the NFs: propolis, Manuka honey, L-arginine, *Calendula officinalis* infusion, and insulin.

Propolis is a resin-like product made by bees. It has a complex chemical composition which depends on the local flora or weather. Flavonoids, phenolic acids and their derivatives are relevant for their antioxidant, anti-inflammatory and antimicrobial properties, which are of great importance in wound healing (11).

Manuka honey acts as a natural re-epithelization agent, which also displays antibacterial properties, due of its major constituent, methylglyoxal. In addition, due to its antioxidant components, Manuka honey also reduces the inflammation and through osmotic mechanisms, absorbs wound exudate, regulates moisture at the wound site and therefore promotes angiogenesis and production of granulation tissue. Finally, wound contraction and epithelialization are promoted (12).

L-arginine is an *alpha*-aminoacid with basic character, containing a guanidine group, which may synergistically promote antioxidant activity when it added to other compounds. More notably, it also promotes epithelialization (13).

Based on its content of flavonoids and saponins, *Calendula officinalis* is found in various pharmaceutical forms (tincture, ointments), used for epithelialization, anti-inflammatory and healing effects (14).

Insulin is a hormone which promotes healing of injured skin if applied topically. It promotes granulation tissue formation and therefore accelerates the contraction of the wound in the healing process (15).

In this work, NFs were prepared *via* electrospinning of a polymer solution consisting of a blend of CS and PEO. After established the optimal electrospinning parameters (concentration of the polymers, ratio CS:PEO, flow rate, distance, voltage), several ACs were further incorporated. To balance the biological effects of the NFs, either a trophic and an antimicrobial (Manuka honey, propolis, insulin) was used together with an angiogenic (L-arginine) or an antioxidant (*Calendula officinalis* infusion) component.

MATERIAL AND METHODS

Reagents

Chitosan (CS) with medium molar weight, polyethylene oxide (PEO) with high molecular weight (1 mill g/mol), L-arginine HCl, and acetic acid (≥99.7%) were purchased from Sigma Aldrich. *Calendula officinalis* was provided by Fares, Romania, propolis by Apiland, Romania, Manuka honey 550+ from Manuka Health New Zealand Ltd and insulin (NovoRapid Penfill 100 U/ mL) from NovoNordisk, Denmark. All other reagents were of analytical grade and were used as received without further purification.

Preparation of CS_PEO and CS-PEO@ACs solutions

The CS_PEO solutions were prepared according to a protocol previously reported (16). Briefly, CS 0.5-3% (wt/v) and PEO 0.5-2% (wt/v) were dissolved in 50% (v/v) acetic acid solution. After the complete dissolution, the ACs (propolis, Manuka honey, L-arginine, insulin) were added to obtain CS-PEO@ACs solutions (CS_PEO@P, CS_PEO@M_L_P, CS_PEO@I_P). A similar protocol was followed for preparation of CS_PEO@P_C solution, with the note that instead of the distilled water used to make the acetic acid solution, a *Calendula officinalis* infusion was used.

Electrospinning of CS_PEO and CS-PEO@ACs solutions

The NFs were prepared using a laboratory-scale electrospinning system (Nanospinner Inovens device) set up with a generator, pump, and a grounded collecting plate used as negative electrode. The CS-PEO and CS-PEO@ACs solutions were electrospun from disposable 5 mL syringe with Luer fitting. The 23-gauge needles were the positive electrode.

Characterization of the CS-PEO and CS_PEO@ACs NFs

The NFs' morphology and average diameter were assayed with Scanning Electron Microscopy (SEM, Inspect S electron microscope with acceleration voltages in high vacuum and a secondary electron beam using energies of 30 keV). All samples were covered with a thin gold film before being analyzed to diminish the electrical charging. After micrographs were taken for all samples, the fiber distribution was determined using the Phenom Fibermetric software. This was carried out by measuring at least 150 fibers from every image (three images from each sample). The data obtained is shown as average diameter ± standard deviation (SD).

RESULTS

În order to obtain randomly-oriented CS_PEO NFs, with small diameter, different electrospinning parameters were changed, such as concentration of CS (0.5-

3% wt/v), PEO (0.5-2% wt/v), CS:PEO ratio (3:1, 2.5:1, 2.5:1.5, 2:1, 1:2, 1:1.5, 1:1, 1:0.5, 0.5:2, 0.5:1.5, 0.5:1), flow rate (1.5-0.5 mL/h), voltage (18-25 kV), the distance between syringe needle and collector (20-27 cm). The results about the morphological aspects of the developed fibers in terms of surface, diameter, distribution and orientation are presented in table I and figure 1.

The optimal parameters to form CS-PEO NFs with proper morphological characteristics (small diameter, continuous aspect, randomly-orientated and distribution was set to CS 1% (wt/v), PEO 0.5% (wt/v), CS:PEO = 1:0.5 and flow rate 0.6 mL/h). Except the flow rate, these parameters were used further to electrospinning the CS_PEO@ACs solutions in order to obtain the corresponding NFs. As results, well-aligned, unidirectional CS_PEO@ACs NFs, with small diameters, no beads and smooth surfaces were obtained (tab. II).

TABLE I.
The electrospinning parameters used for preparation of CS_PEO NFs

CS (g/100 mL)	PEO (g/100 mL)	Flow rate (mL/h)	Distance (cm)	Voltage (kV)	Notes
3	1	0.75	25	18-25	dripping, NFs with large diameter, >600 nm
3	1	1	25	18-25

DISCUSSION

Setting up a yield-effective electrospinning process is a time-consuming operation because it implies the adjustment of every parameter involved in the process. To sum up all obstacles that were encountered in the optimization phase, not only the difficulty is to be mentioned, but also the solution that was found to counter it.

Longer stirring times of polymeric solutions also helped against the formation of droplets, by increasing the homogeneity of the electrospinning solutions. Therefore, a minimum 36 h was the optimal time to ensure proper conditions. When no fibers seemed to be forming, the electric field was increased to values higher than 22 kV (16). In case of discontinuous fiber formation, an increase of both the electric field and flow rate helped with to optimize the process. A particular case also appeared when using CS 2% (wt/v), forming of flat fibers. This was countered by increasing the distance between the syringe needle and the collector.

Often the electrospinning of the polymeric solution leaded to the formation of beaded chains. Since the humidity was kept at low values during the experiments (17-20%) and the room temperature was at a constant value of 21-22℃, other values needed to be adjusted. When changing the molecular weight of CS to a higher one, little to no fibers were formed, therefore the experiment resumed at the initial medium molecular weight. The key to the success of the experiment was adjusting the polymers (CS, PEO) concentrations and the ratio. As can be seen in fig. 1, higher concentration led to wider fiber diameters, and rough surfaces of the fiber. A smooth surface was obtained at a ratio of 1:0.5 (CS : PEO) and a maximum total concentration of 1.5% (wt/v) (CS 1% PEO 0.5%) polymer solution. The higher the weight concentration of the chitosan, the more the solution seemed to be extruded from the syringe rather than simply flow. Although an increase of the electric field seemed to help with this problem, there were still fragments which seemed to be building at the tip of the needle. Also, in this case fibers seemed to be climbing back from the collector to the needle. This was another factor that contributed to choosing the medium molecular weight CS (17).

The SEM analysis determined for optimized types of NFs incorporating ACs that they had smooth surface with no beads, possibly due to the properties induced by the ACs. Indeed, the average diameter has increased after adding the ACs into the CS_PEO matrix, our results agreeing with other literature data (18).

A more comprehensive analysis through SEM (fig. 1) shows a compact 3D nanofiber mesh containing randomly settled fibrils, which generate an irregular surface with an interwoven porous frame. This 3D frame shapes a large contact surface with docking points for cell-NF interaction helping cellular processes as adhesion, migration, and proliferation (19). Also, electrospun NFs have also given a unique means for Manuka honey delivery while contributing as artificial matrix for wound healing thanks to their geometry (20).

The widest diameter was noted for the CS_PEO@M_L_P (201 ± 6 nm), while for the NFs incorporating propolis this value was approximately 170 nm (169 ± 12 nm for CS_PEO@P, 170 ± 11 nm for CS_PEO@P_C, and 169 ± 11 nm for CS_PEO@I_P). The only statistical difference, when compared with CS_PEO (163 ± 16 nm) appeared for CS_PEO@M_L_P (p value <0.05). This may be due to honey's viscous properties and smaller possibility for the electrospinning jet to stretch rapidly and permit the solvent to evaporate in a very short amount of time.

Other studies included NFs that incorporate Manuka honey up to 10-20% (wt/v), the average diameter also displayed a rise from 357 to 400 nm (18). This data also supports our results and demonstrates the successful incorporation of the Manuka honey into the CS_PEO matrix.

CONCLUSIONS

New blended NFs consisting of CS and PEO incorporating ACs were designed, and their obtaining process was optimized, considering the morphology and fiber diameter as key elements to successful preparation. After the optimization of the electrospinning process, in terms of the polymer (CS, PEO) concentration, polymer ratio (CS:PEO), flow rate, voltage and distance between syringe needle and collector, proper CS_PEO NFs were obtained. Based on optimized process of CS_PEO NFs new CS_PEO@ACs NFs were

developed. The results revealed that the Manuka honey-based NFs (CS_PEO@M_L_P) displayed a good diameter, smoother fiber morphology and homogenous distribution that could be useful for further applications. The new blends are a starting point to explore new possibilities for modern wound healing therapy and can be candidates for further tests regarding wound healing potential.

NEWS

VITAMIN D AND OPHTHALMOPATHIES. A REVIEW

The importance of hydroxycholecalciferol as one of the liposoluble vitamins is known in the prevention and treatment of metabolic bone diseases (rickets, osteomalacia, osteoporosis). In recent years, however, information has increased on the importance of vitamin D3 in numerous organ systems and in the pathogenesis of various diseases, e. g. ophthalmopathies. The immunological functions of vitamin D3 are the subject of studies dealing with autoimmune optic nerve disorders and their results appear to have a positive effect on demyelinating diseases. It also plays an important role in maintaining the thickness of the retinal nerve fiber layer, but its additional administration has not been successful. It appears that sufficient serum vitamin D3 levels may protect patients from deterioration in the form of a further attack of demyelination. The course of diabetic retinopathy is probably also influenced by vitamin D3, by correlating the fact that its receptor and the enzymes of its metabolism are expressed on the retina. Low serum levels of vitamin D3 may even trigger age-related macular degeneration. Conversely, higher dietary intake of vitamin D3 may positively affect neovascularization. The optimal level of hydroxycholecalciferol is between 60 and 200 nmol /l, the severe deficit represents a decrease below 25 nmol/l. However, the demonstration of its protective character in connection with the mentioned diseases of the retina and optic nerve will require a sufficient number of studies to confirm the facts found so far about this rediscovered vitamin (Hribová P, Sotak S. Vitamin D and ophthalmopathies. A review. *Ceska a slovenska oftalmologie: casopis Ceske oftalmologicke spolecnosti a Slovenske oftalmologicke spolecnosti* 2022; 2: 1001-1004).

EVALUATION OF GINGIVAL EPITHELIAL CHANGES THROUGH OPTICAL COHERENCE TOMOGRAPHY AT PERIODONTAL PATIENTS WEARING FIXED DENTAL PROSTHESIS

EVALUATION OF GINGIVAL EPITHELIAL CHANGES THROUGH OPTICAL COHERENCE TOMOGRAPHY AT PERIODONTAL PATIENTS WEARING FIXED DENTAL PROSTHESIS (Abstract): The current *in vitro* investigation **aim** is to identify changes in optical coherence tomography images of gingival tissue samples by analyzing the epithelial thickness and its pixel density, trying to find connections with the gingival inflammatory condition of periodontitis patients wearing fixed dental prosthetics. **Material and methods**: A total of 25 patients were admitted in this study, and were undergone a clinical periodontal examination, where probing depth (PD) and gingival inflammation index (GI) were recorded, and gingival samples also were collected from teeth with and without dental prosthesis, consequently two groups were obtained: control group CG-25 gingival samples from the teeth not wearing a dental prosthesis and prosthetic group PG -25 gingival samples from the teeth wearing a dental prosthesis. The samples were analyzed through optical coherence tomography. **Results**: The results show a statistically unsignificant difference in PD between the two groups, but also a statistically significant difference in GI between the two groups. A statistically significant difference was found between the epithelial thickness (ET) between the two groups. A strong inverse and statistically significant correlation were discovered between ET and GI. **Conclusions**: The OCT analysis has proved useful in showing that there could be a possible association between periodontal changes and fixed dental prosthesis, and it also showed that fixed prosthodontics has a significant negative impact on the periodontium, making possible not only the treatment but the prevention of periodontal clinical changes in patients wearing dental prosthesis, thus improving the quality of life of these patients.
Keywords: PERIODONTAL, OCT, DENTAL PROSTHESIS.

Periodontal disease is an inflammatory condition that affects the teeth's supporting tissues. The illness is caused by bacteria and begins at the gingival level, when perio pathogen microorganisms create inflammation of the soft tissues around the tooth. The inflammation advances progressively into the deeper structures that support the teeth. Periodontal pockets build around the tooth as the disease progresses, containing more bacterial plaque and calculus deposits, thus exacerbating the inflammation (1).

If the onset of the disease is influenced by the microbial composition of the subgingival biofilm and the type and intensity of the host immune response, subsequently, a series of local and systemic predisposing factors are involved. Generally, local risk factors act as bacterial biofilm retentors and prevent the patient from efficiently removing plaque deposits. These local risk factors include morphological abnormalities such as crowded teeth and malocclusions, dental treatments such as orthodontic and prosthodontic appliances and dental calculus. Most local risk factors are modifiable and correctable so as to offer to the patient and practitioner a favorable status for a good plaque control (2).

The technology of optical coherence tomography (OCT) generates optical sectional pictures. Low-coherence interferometry is used to determine the echo time delay and magnitude of backscattered light reflected by a given studied surface. The laser beam directed at the surface is reflected differently by the surface's structural irregularities, resulting in interferences that are detected by a sensor (3).

OCT has been researched in preventive dentistry as a technique to check the integrity of dental sealants used in youngsters (4). It has been employed in endodontics as an adjuvant approach for identifying root canals in teeth with unique endodontic anatomical systems and in restorative dentistry to identify tooth cracks, their morphology, and location, making it easier to diagnose and treat challenging dental disorders such the fractured tooth syndrome (5).

The experimental use of OCT in periodontology found that OCT can visualize periodontal pockets and attachment loss, and that it can even be used to measure pocket depth utilizing axial resolution of the images, with findings that are comparable to manual periodontal probing(6). Using the measurement of gingival tissues thickness or pixel density of images, OCT proved to be useful in assessing inflammation in epithelial or connective tissue in periodontal patients with systemic diseases (7).

The current in vitro investigation intends to identify changes in optical coherence tomography images of gingival tissue samples by analyzing the epithelial thickness and its pixel density, trying to find connections with the gingival inflammatory condition of periodontitis patients wearing fixed dental prosthetics.

MATERIAL AND METHODS

Patients. The subjects for the study addressed the Periodontology Department at Craiova University of Medicine and Pharmacy in Romania from 01.11.2018 to 01.06.2019. The Ethics Committee permission of the University of Medicine and Pharmacy of Craiova, number 104/ 22.10.2018, was acquired for the study, as well as written informed consent from all participating patients. All participants were told about the study's purpose and that it was being carried out in line with the Hel-

sinki Declaration.

To be included in this study, all periodontal patients must have been diagnosed with periodontitis, had at least one periodontal pocket ≥ 5mm on a tooth wearing a dental fixed prosthesis in the lateral premolar-molar region, allowing for standardized gingival tissue collection, regardless the material from which the prosthesis were made or their age and at least one periodontal pocket ≥ 5mm on the correspondent tooth from another premolar-molar region without dental prosthesis. Patients were diagnosed with periodontitis (8) at the Periodontology Department, had initial periodontal therapy, and then underwent surgical periodontal therapy following a reevaluation. To reduce individual variability, all patients underwent periodontal examinations by the same previously trained practitioner. Criteria for exclusion: diagnostics of diabetes, rheumatoid arthritis, liver or cardio-vascular diseases, treatment with non-steroidal anti-inflammatory medication or antibiotics in the three previous months, pregnancy, smoking.

A total of 25 patients were admitted in this study, aged 32-62 years (51.04±9.87), 14 females (F), 11 males (M). The patients were undergone a clinical periodontal examination and gingival samples were collected from teeth with and without dental prosthesis, as mentioned above and two groups were obtained: control group CG-25 gingival samples from the teeth not wearing a dental prosthesis and prosthetic group PG -25 gingival samples from the teeth wearing a dental prosthesis.

Clinical Periodontal parameters. From each patient, the probing depth (PD) expressed in millimeters was collected from the periodontal chart for every tooth included in the study, calculating the average for each group and the gingival inflammation index (GI – Loe and Silness, 1963) expressed in grades 0-3 (0 = normal gingiva; 1 = mild inflammation: slight change in color, slight edema, no bleeding on probing; 2 = moderate inflammation: redness, edema, and glazing, or bleeding on probing; 3 = severe inflammation: marked redness and edema, tendency toward spontaneous bleeding, ulceration) also calculated as the average for each group (9).

Gingival tissue sampling. Gingival samples were taken from the periodontal pocket during periodontal surgery conducted as part of a conventional periodontal treatment for patients with periodontal disease. Samples were standardized to a square dimension of 3/3 mm. They were then put in 10% formalin and refrigerated at +8 degrees Celsius until their processing.

OCT analysis. Thorlabs (Thorlabs Inc., New Jersey, USA) provided the OCT setup, model number OCS1300SS, with a power swept laser source at a central wavelength of 1310 nm, a spectral band-width of 100 nm, and an average power of 12 mW. The gingival samples were withdrawn from their containers, and the residual formalin solution was dried from their surfaces. They were then placed on Petri dishes with the gingival epithelium facing upwards and subjected to the OCT system's laser beam.

The samples were scanned in air with axial resolutions of 12 m and lateral resolutions of 15 m. The 3 mm square samples were scanned across a range of 1024 x 1024 x 512 pixels (length, width, depth, x:y:z), with the refraction index set at 1.41 (10). Each sample scanning yielded 512 sections, which were stored as JPEG images. The photos were analyzed using ImageJ, a free image processing program provided by the National Institutes of

Health in the United States. For the pixel density study, five consecutive photos were chosen from a total of 512 for each sample, including the median image (256), two prior (254, 255) and two following images (257, 258), and the density was assessed in terms of both pixel counts and gray-scale values (7). Consequently, 125 images were investigated in each group (CG and PG).

A measuring segment in the form of a linear shape was inserted perpendicular to the center of each picture, from the higher to the lower edge of the gingival epithelium (fig. 1). Through the ImageJ application, the length of the segment, representing the epithelial thickness (ET), was calculated in µm. The application produced a set of data reflecting the gray-scale intensities of the pixels (7), as well as the number of pixels present in each examined region and the length and area filled by the measurement segment, which were then recorded in *Microsoft Excel* format. The average values (Pix) were computed for each research group.

Statistical analysis. The data were expressed as mean ± standard deviation (SD). The t-Student test was used to compare the acquired data for the two research groups, different characteristics of the research groups were correlated using the Pearson statistical correlation test, with the statistical significance level set at $p<0.05$ (*SPSS version 19.0*, IBM, USA)

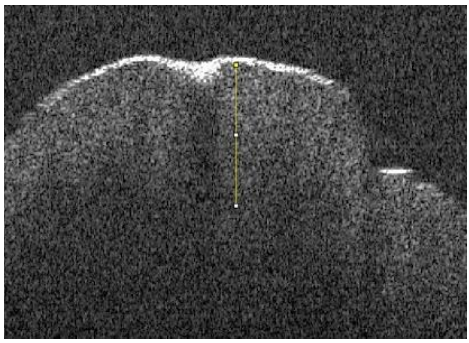

Fig. 1. Measurement of ET and Pix on the OCT image of the periodontal patients gingiva

RESULTS

The results show a difference in PD between the two groups, but statistically unsignificant ($p>0.05$) but also a statistically significant difference in GI between the two groups ($p=0.046$). A statistically significant difference was found between ET ($p=0.003$) and Pix ($p=0.000013$) between the two groups.

A strong and statistically significant correlation was found between Pix and GI in each group and a strong inverse and statistically significant correlation was discovered between ET and GI (tab. I).

DISCUSSION

Maintaining a healthy periodontal status at the level of teeth that benefit from restorations with edges in contact with the free gingival margin is a challenge for practitioners, as the odonto-periodontal unit is constantly affected by the microbial flora, as its load can be stimulated by dental restorations (11). The most common mechanism by which prosthetic restorations may affect the status of the marginal periodontium is by favoring the accumulation of bacterial plaque (12).

The positioning of the edges of the crown in relation to the free gingival margin, the material from which the dental prosthetic restoration is made, its contour and profile, all these elements influence the health of the periodontal structures (13). In our study, the PD of teeth wearing a dental prosthesis are higher than that of those without it, but the differences are not significantly, while the GI in group PG is significantly higher than in group CG, suggesting the influence of dental prosthesis on the gingival inflammatory status, possibly by plaque retention and, consequently, the exacerbated inflammation.

There are histological changes that can be observed within the inflamed gingival epithelium, with the appearance of inflammatory oedema and the decrease of tissue density. The OCT assessment of gingival tissue samples suggests an association between pixel density and the degree of periodontal inflammation, as it was previously shown in periodontal patients suffering from systemic conditions (7). In the present study, it was found that Pix inversely correlated with GI, sustaining the previous finding. The images of the gingival samples, obtained by OCT revealed that the pixel density of the epithelium was lower in PG samples as compared to those of group CG. This fact could be explained by the exacerbated periodontal inflammation in the gingiva of teeth wearing a dental prosthesis.

The major epithelial thickness (MET–distance between the external epithelial surface and the epithelial crista tip) and the epithelial base thickness (EBTdistance between the external epithelial surface and basal membrane located between two cristae) were evaluated on the histological or OCT images of the gingiva of periodontal patients (14-16) or the epithelial thickness (ET) in different areas of marginal gingiva (17). These studies shows that the inflamed epithelium is thinner as our study found also in PG, between the ET and GI being found an inverse correlation. These results sustain the idea that the presence of dental prosthesis exacerbates the inflammation in periodontitis patients.

However, the study was limited in the number of participating patients, the purpose was to draw attention to the possible influence of dental prosthesis, regardless the material or the initial placement of prosthesis margins on the periodontal inflammation in the presence of the preexisting periodontal diagnosis.

CONCLUSIONS

The OCT analysis has showed that there could be a possible association between epithelial inflammatory changes and fixed dental prosthesis, and it also showed that fixed prosthodontics has a negative impact on the periodontium, making important not only the treatment but the prevention of periodontal clinical changes in patients wearing dental prosthesis, thus improving the quality of life of these patients.

INFLUENCE OF BODY MASS INDEX ON DENTAL DEVELOPMENT AND GINGIVAL INFLAMMATION IN CHILDREN OF 6-12 YEARS OLD (Abstract): **Aim**: Our study aims to assess the influence of BMI (Body Mass Index) on dental development and gingival inflammation in children aged 6-12 years old. **Material and methods**: The study was conducted on a group of 153 children aged 6 to 12 years, which were divided into three categories: normal weight, overweight and obese patients. Dental development estimation was performed using the Demirjian method, by using orthopantomographies. For each patient, chronological age, BMI, plaque index (PI) and gingival index (GI) were recorded. **Results**: The mean difference between chronological and dental age for the whole study group was 0.66±0.5 years. The mean value of the difference between chronological age and dental age for overweight and obese subjects was 0.81±0.43 years and 1.1±0.45 years, respectively. A significant correlation between BMI and GI was observed for male subjects. No correlations were found between BMI and chronological age, or between BMI and dental age. It was found correlation between BMI and the difference between chronological age and dental age. **Conclusions**: In the group of obese children there was a greater difference between chronological age and dental age compared to overweight and normal weight children, indicating that permanent teeth are likely to erupt at a younger age among obese and overweight pediatric patients. **Keywords**: GINGIVAL INFLAMMATION, DENTAL DEVELOPMENT, OBESITY.

Dental development is a complex biological process, studies showing that obesity can be associated in many cases with an acceleration of odontogenesis, regardless of gender or socioeconomic status (1-4).

Obese pediatric patients have been shown to have low levels of growth hormone and, at the same time, increased lev-

els of insulin-like growth factor1 (IGF-1) (5). Studies suggest that IGF-1 is associated with accelerated growth and development by suppressing the activity of the hypothalamic-pituitary system, which may lead to steadily decreasing growth hormone levels (5, 6).

Body Mass Index (BMI) is the most widely used indicator of obesity (National Institute for Clinical Excellence, 2006) (7).The Body Mass Index could be calculated dividing the weight in kilograms by the square of height in meters.

Recent studies also suggest that obese adolescents exhibit early development of craniofacial massif (8), which may lead to worsening of the existing dento-maxillary anomaly, requiring orthodontic intervention through interceptive therapeutic methods (9).

Numerous methods have been developed to assess dental age in children and adolescents. The method described by Demirjian in 1973 (10) is the most widely used method of dental age assessment due to its accuracy and feasibility. The effectiveness of the Demirjian method has been evaluated among different ethnicities (11-14). The correlation between dental development, height and weight has also been assessed and found to be a significant correlation in many of the studies (2, 15-18).

Our study aims to assess the influence of BMI on dental development and gingival inflammation in children aged 6-12 years.

MATERIAL AND METHODS

The study was conducted on a group of 153 children aged 6 to 12 years, 70 male and 83 female patients who presented to the dental office for routine dental treatments. For the study to be carried out, the approval of the Ethics Committee of University of Medicine and Pharmacy from Craiova, Romania was obtained (No.14/21.01.2019). and the informed consent was signed by the tutors.

Inclusion criteria: pediatric patients with no history of systemic disease, who had not received orthodontic treatment in the past and whose panoramic radiological investigations provided good quality images. Exclusion criteria: patients with an incomplete medical history, congenital malformations such as cleft lip and palate (whether they were surgically corrected or not), developmental dental anomalies or patients with previous extractions of permanent teeth, and radiological investigations of poor quality.

Dental age estimation was performed on the 153 orthopantomographies using the Demirjian method (10) based on the eight stages of development of the tooth, starting with mineralization from the cusp tip to apex closure. As the method involves a degree of subjectivity, the analysis of each orthopantomography was performed by an examiner who transformed the scores that have been obtained using gender-specific conversion tables.

Chronological age was determined according to the date of birth of each patient.

The BMI was calculated as the ratio of weight to height (expressed in kg/m^2). Patients' weight status was assessed using the International Obesity Task Force (IOTF) recommended classification system for childhood obesity (19). The study group was divided into three categories: normal weight, overweight and obese patients.

The clinical examination was performed by a single well-trained dentist.

The bacterial plaque index (PI) (20) was used to assess supragingival plaque deposits, which has a grading scale with values

from 0 to 3.The Gingival Index (GI) scores on a scale of 0 to 3, where 0 - normal appearance to 3 - severe inflammation characterized by oedema, redness and spontaneous bleeding (21).

For statistical analysis, *Graph Pad Prism 9.4.0* was used. The data are described as mean ± standard deviation (SD) for continuous variables and as number (percentages) for discrete variables. The direction and magnitude of correlation were assessed with Pearson or Spearman correlation or 3-way ANOVA, depending on that values from variables are sampled from populations with a Gaussian distribution or not. Data were tested for normality using Shapiro-Wilk test.

RESULTS

The mean age of the study group was 9.22±1.69 (54.2% female and 45.8% male), while the background was predominantly urban. The mean weight with a value of 32.88±7.34 (72.5% of them with normal weight) (tab. I)

The mean difference between chronological and dental age for the whole study group was 0.66±0.5 years. The mean value of the difference between chronological age and dental age for overweight and obese subjects was 0.81±0.43 years and 1.1±0.45 years, respectively (tab. I). The differences between the two ages according to gender are shown in Table II.

A low correlation was identified between BMI and PI, on the limit of statistical significance for male patients (ρ=0.23, p=0.055), but the data could not be correlated for the female patients (ρ = -0.119, p=0.286).

A significant correlation between BMI and GI was observed for male subjects (ρ= 0.398, p=0.001), while for the female group there was none (ρ=0.167, p=0.131). No statistically significant correlation was identified between GI and the difference between chronological age and dental age (ρ=0.059, p=0.468).

TABLE I.

Batch distribution according to variables analyzed

Variables analyzed	
Chronological age	
Mean (±SD)	9.22 (±1.69)
Range	6-12
Age category	
6-9 years old	61 (39.9%)
9-12 years old	92 (60.1%)
Dental age Mean (±SD)	9.87 (±1.8)
Difference between chronological age and dental age Mean (±SD)	
whole study group	0.66 (±0.5)
normal weight children	0.58 (±0.5)
overweight children	0.81 (±0.43)
obese children	1.1 (±0.45)
Gender	
Male	70 (45.8%)
Female	83 (54.2%)
Background	
Urban	124 (81%)
Rural	29 (19%)
Weight	32.88 (±7.34)
Height	135.05 (±10.15)
BMI	
Normal weight	111 (72.5%)
Overweight	35 (22.9%)
Obese	7 (4.6%)
Plaque Index (PI)	
0	24 (15.7%)
1	72 (47.1%)
2	54 (35.3%)
3	3 (2%)
Gingival Index (GI)	
0	55 (35.9%)
1	68 (44.4%)
2	29 (19%)
3	1 (0.7%)

Also, no correlations were found between BMI and chronological age (ρ=-0.101, p=0.213), or between BMI and dental age (ρ=-0.02, p=0.81), but there was between BMI and the difference between chronological age and dental age (ρ=0.281, p<0.001). Thus, increased BMI is associated with accelerated dental development in children aged 6-12 years old.

TABLE II.
Difference between chronological age and dental age by gender

AGE	Male (n=70)	Female (n=83)
Chronological age Mean (±SD)	9.36 (±1.73)	9.1 (±1.66)
Dental age Mean (±SD)	9.97 (±1.82)	9.79 (±1.79)
Difference between the chronological age and the dental age Mean (±SD)	0.62 (±0.57)	0.69 (±0.42)

No statistically significant correlation was identified between age, gender and BMI. The distribution is normal with the mean=0.66 and SD=0.50. No possible outliers were detected for the dependent variable. Dental development was significantly accelerated with increasing BMI, but not after adjusting for age and gender (p>0.05). These three factors did not correlate in terms of acceleration of the dental development.

Accelerated dental development was observed to be correlated with BMI only in male patients (ρ=0.363, p=0.002), but for female patients the correlation was low and to the limit of statistical significance (ρ=0.208, p=0.059).

The magnitude of the correlation between variables differs by gender without being statistically significant. A greater difference in dental development can be observed for female patients in the age group of 9-12 years old compared to the age group of 6-9 years old(figs. 1, 2)

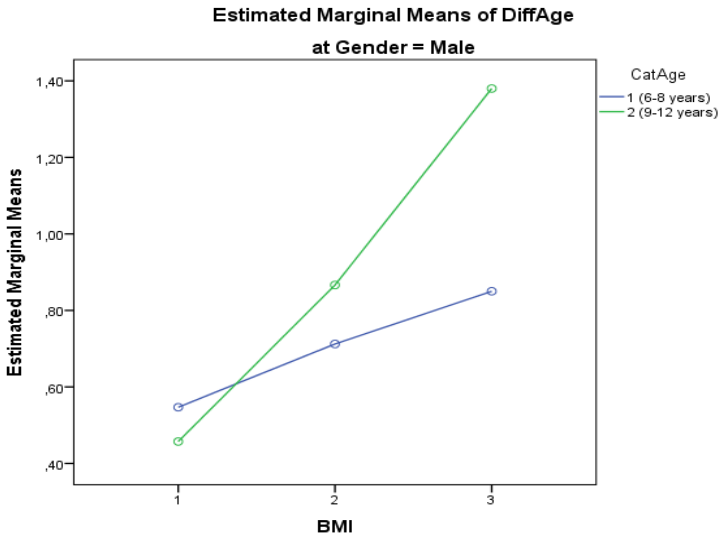

Fig. 1. Correlation between BMI and difference between chronological age and dental age for male patients

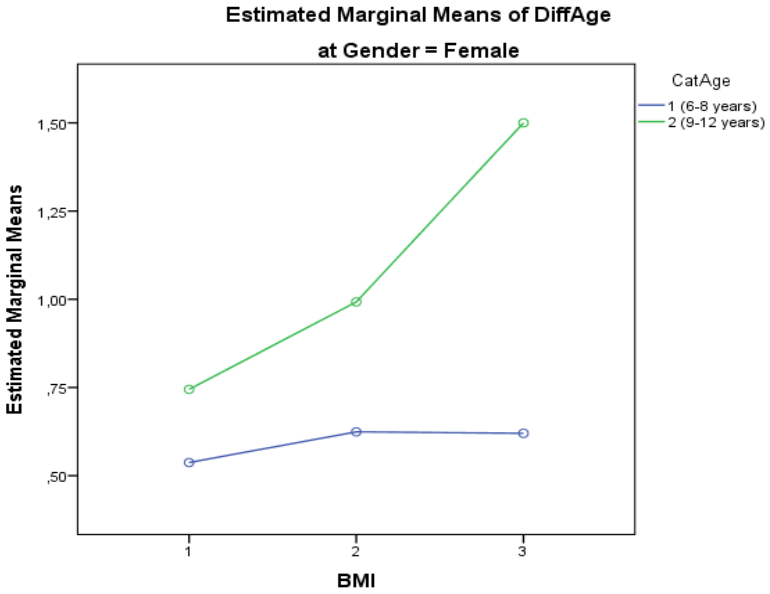

Fig. 2. Correlation between BMI and difference between chronological and dental age for female patients

DISCUSSION

Childhood obesity is frequently associated with accelerated dental development, an increased incidence of carious lesions located mainly on permanent molars, an increased risk of periodontitis in late adolescence and early adulthood (22). In the study by Hedayati Z *et al.*, the dental age of normal weight children was found to be lower than the chronological age, while among obese children the dental age was higher than the chronological age and there was a direct correlation between BMI and the process of dental development (3), data which were not according to the study by Panchbhai A *et al.* in which a negative, non-significant correlation was observed between BMI and mean dental age (23).

Our study found a significant positive correlation between accelerated dental development and BMI values, results also found in other studies (3, 15, 17, 24-28). Also, studies have reported accelerated dental development/age in obese children compared to children with weight within normal values (2, 29, 30).

In contrast to the results of the present study, it was reported a negative correlation indicating delayed tooth eruption for the group of overweight and obese children of 6-7 years old compared to the group of children with normal weight, authors explaining these results through the differences in ethnicity, racially, and dietary habits between Indian and Western population (31). Also, Khan *et al.* observed that the dental eruption time of Pakistani children are different in many aspects with to other nationalities. (32).

The results of our study show that accelerated dental development correlated with the BMI in male patients. In some studies, it was shown that among female patients, the difference between chronolog-

ical and dental age in both obese and normal weight patient groups was greater compared to male patients (24, 25). Du-Plessis *et al.* evaluated the correlation between BMI and dental development by gender and observed a non-significant difference between boys and girls (28).

Early onset of dental development refers to the importance of establishing and performing proper oral hygiene in children from an early age. In a longitudinal study (17), it was observed that overweight pediatric patients have a higher number of erupted teeth compared to other children of the same age ($p<0.001$) and also that there is a correlation between BMI and oral health in children and adolescents. Evan in our study it was found a low correlation to the limit of statistical significance between BMI and PI, there are other results that showed a bad attitude of obese/overweight children and teenagers towards oral hygiene (33).Our study showed significant correlation between gingival inflammation and BMI for male patients, possibly due to a combination of factors: not only to the inappropriate attitude toward dental hygiene but to the metabolic and inflammatory changes (33).

If permanent teeth erupt early, there is concern that the young patient will not have the ability and responsibility to brush them correctly. Therefore, their poor oral hygiene will result in an increased frequency of carious lesions in the mixed and permanent dentition. In addition, the timing of eruption could affect the planning of orthodontic therapy. If interceptive orthodontic treatment is recommended, which may result in altered growth patterns (34), the timing of therapeutic intervention will involve a reassessment of the clinical case to consider gender and BMI (8).

CONCLUSIONS

In the group of obese children there was a greater difference between chronological age and dental age compared to overweight and normal weight children, indicating that permanent teeth are likely to erupt at a younger age among obese and overweight pediatric patients.

NEWS

IS THE PATIENT WITH PSORIASIFORM SKIN LESIONS SUSCEPTIBLE TO PARADOXICAL REACTION UNDER THE TNF A ADMINISTRATION?

Paradoxical reactions (PR) are immune-mediated disorders that would normally respond to the biologic therapy. The exacerbation of existing psoriasis after administration TNF-α antagonist is a well-described problem. This study analyzes, 125 patients during the therapy with a TNF antagonist. Of these, 14 patients experienced PR under TNF antagonist therapy (adalimumab, infliximab, certolizumab pegol, etanercept). Thirteen patients discontinued TNF antagonist therapy and only one patient continued the biologic therapy. The present study showed no improvement in patients who were switched to another TNF antagonist, except one patient who was switched to infliximab. In addition, this study suggests that focal infections in psoriasis patients may be a risk factor for the development of PR due to TNF antagonist administration. Our study demonstrates that there are some disease (acrodermatitis continua of Hallopeau and palmoplantar pustular psoriasis) which may predispose the patients to PR under TNF antagonist therapy. Finally, this finding has relevance for the physician to recognize these clinical problems and helps to identify the potential therapeutic targets (Miho Mori, Rie Tobita, Chizu Egusa, *et al*. Clinical background of patients with psoriasiform skin lesions due to tumor necrosis factor antagonist administration at a single center. *J Dermatol* 2021; 48(11): 1745-1753).

OPTIMIZATION OF PCR BASED ON DNA QUALITY IN ONCOLOGICAL RISK POPULATION DNA SAMPLES FROM BENIN

OPTIMIZATION OF PCR BASED ON DNA QUALITY IN ONCOLOGICAL RISK POPULATION DNA SAMPLES FROM BENIN (Abstract): In Benin, like other countries in the sub-Saharan region, breast cancer ranks first among all cancers. **Material and methods**: A highly heterogenic collection of 120 DNA samples from breast and prostate cancer patients and matched controls was available for further study on detection of BRCA1/2 gene mutations pattern. **Results**: Initially, the PCR amplification of BRCA1 exon 5 was performed for all samples, with poor results in terms of PCR efficiency. Only about a third of the samples showed visible bands of the expected size and with no contamination. A re-evaluation of DNA samples showed high variability on DNA concentration and quality, due to different extraction methods, sample origin and preservation condition. **Conclusions**: Our study primarily illustrate that DNA extracted from different tissue by different extraction methods may be damaged but still usable, by increasing the DNA amount in the PCR reactions and adjusting the other PCR parameters. However, appropriate caution should be exercised when analyzing samples derived from different tissue sources. By appropriate optimization, heterogenous samples can be simultaneously used for PCR amplifications with single parameters.
Keywords: BRCA1, BREAST CANCER, PROSTATE CANCER, MULTIPLEX-PCR.

Breast cancer (BC) is now ranked as the most common cancer worldwide, with an incidence of 2.3 million new cases (11.7%) and it's continuously increasing during the last decade. Breast cancer mortality rates have markedly increased across Africa where estimated age-standardized rates in 2020 ranged from 20 deaths per 100,000 women across Northern Africa to 27 deaths per 100,000 women in Western Africa (1). In Benin, like other countries in the sub-Saharan-region, breast cancer ranks first among all cancers of all sexes. Its incidence is constantly increasing with a

high mortality rate (2).

Knowledge of genetic factors contributing to BC risk has important implications for patients and their families both for genetic counseling and for potential access to new therapies, which improve survival and reduce side effects. BRCA1 (3) and BRCA2 (4) are major cancer predisposition genes, associated with a greatly increased risk for breast cancer development, with risk estimates ranging from 59-87% for BRCA1 and from 38-80% for BRCA2 mutations (5). Screening for mutations in these two genes is now standard practice for Hereditary Breast and Ovarian Cancer Syndrome (HBOC) cases in Western Europe and North America and allows early detection and efficient medical follow up and treatment (6, 7, 8, 9). However, in sub-Saharan Africa the exact burden of cancer mutations remains largely unknown and understudied. A few reports on BRCA1 and BRCA2 mutations and sequence variations unique to Africans has been reported: the presence of 3 common BRCA1 mutations: 185delAG in exon 2, 4184del4 in exon 11, and 5382insC in exon 5 was reported in black South African women with breast cancer; 2 novel BRCA1 truncating mutations, Q1090X and 1742insG in Nigerian breast cancer patients (10); four BRCA1 missense variations; one BRCA2 truncating mutation, 3034del4, previously unreported in anyone of African descent; and 20 no truncating variants were detected in BRCA2 (11). However, no study was conducted in Benin, so to start some genetical screening on Beninese breast cancer patients is very important in order to address these knowledge gaps.

Through to technological advances, NGS, Sanger and others molecular screening techniques are now available, there are still expensive and practically hard to use in low economical developed countries. For this reason, the polymerase chain reaction (PCR) technique remains the basis of molecular analysis in these countries.

To overcome the inherent disadvantage of cost and to improve the diagnostic capacity an allele specific multiplex PCR method for detection of BRCA1 5382insC mutation has been developed by Pak Cheung R and *et al.* (12). Early studies highlighted the obstacles that can jeopardize the production of sensitive and specific multiplex assays. Although more recent studies have provided systematic protocols and technical improvements for simple test design the method still need optimization to enhance sensitivity and specificity and to facilitate the application of multiplex PCR for mutation detection in specific conditions.

The objective of this paper was the optimization of the PCR amplification process using a heterogeneous DNA collection from different tissue sources of breast and prostate cancer (PC) patients and controls from Benin. BRCA1 Exon 5 amplification is simple and relatively rapid method for DNA quality testing. This assay was used for a bigger study to investigate the presence of BRCA1 5382insC and other common worldwide mutations in the Beninese population with cancer risk.

MATERIAL AND METHODS

A highly heterogenic collection of 120 DNA samples provided by University of Abomey Calavi, Benin and represent consecutive series of breast cancer (BC) patients (tissue and blood n=38) prostate cancer (PC) patients (blood, n=32) and their respective sex, age, and ethnicity matched controls (39 blood control for BC

patients and 11 blood control for PC) was evaluated. The micro fragments of breast cancerous tissues were collected by the oncologist surgeon by micro biopsies by the patients diagnosed with breast cancer were treated at the National University Hospital Center-HKM (CNHU-HKM) of Cotonou (Benin) in the department of Visceral Surgery and Oncology. The blood of patients with breast and prostate cancer was collected in other hospitals in Benin.

Genomic DNA was extracted from peripheral blood collected on EDTA, by 2 different methods: using the Wizard™ Genomic DNA purification kit (Promega Inc, Madison, WI, USA) and using phenol chloroform method.

Two 3 mL samples were processed in parallel, for the first method and DNA was eluted in 1 mL TE Buffer.

The phenol-chloroform method was used both to extract DNA from microtissue and blood cells. Lysis buffer containing proteinase K (20 mg/mL) and RNAse was added to the sample to disaggregate the cell membrane. Then, an equal volume of chloroform was added to the collected upper aqueous phase, followed by another centrifugation (10,000 rpm at 4°C for 10 min). The supernatant was collected in a new Eppendorf tube and the DNA was extracted as a pellet after addition of ice-cold 96% ethanol and incubation at -20°C for 4h (13).

DNA amount and quality was estimated by spectrophotometry, using Biochrom WPA Biowave II UV/Visible Spectrophotometer.

Exon 5 of BRCA1 gene was amplified in 20 µL final volumes, starting from 50 ng of gDNA. The amplification mixture included 1 × PCR buffer, forward and reverse primers, dNTPs, and 2 U of *Taq* DNA polymerase. Thermal profile used for amplification was a first denaturation step at 94°C for 5 minutes, followed by 35 cycles: denaturation at 94°C for 20 seconds, annealing at 54°C for 30 seconds, and extension at 72°C for one minute. Final extension was accomplished at 72°C for 7 minutes.

Allele-specific multiplex-PCR was performed for detection of 5382insC BRCA1 mutation, using the 3-primers multiplex-PCR as reference method (14, 15). PCR was finally performed in a final volume of 20 µL, using 50 ng gDNA and containing 0.5 units of GoTaq Polymerase (Promega) in appropriate 1X no magnesium containing buffer, 3.25 mM MgCl2 (2.6 µL used from a 25 mM stock solution), 0.2 µM of each primer (0.4 µL of 0.01 mM solution for common reverse, wild-type specific forward and mutant-specific forward), 0.2 mM each dNTP (0.4 µL of a pre-mixed dNTP solution with 10 mM each), and nuclease-free water to final volume of 20 µL.

The amplifying program was optimized alternatively on thermocyclers as Mastercycler™ Gradient (Eppendorf AG, Hamburg, Germany) (12). Each PCR reaction consisted of an initial denaturation of 10 minutes at 95°C, followed by 35 cycles of 15 seconds of denaturation at 94°C, 15 seconds of annealing at 57°C, and 30 seconds of extension (with an increment of 1 second for each subsequent cycle) at 72°C, and a final extension step of 5 minutes at 72°C using GeneAmp® 9700 PCR System, Applied Biosystems.

Amplification aliquots were migrated, at 5 V/cm on 2% or 3% agarose gels containing 0.5 µg ethidium bromide for 1 mL gel solution. Following electrophoresis, gels were visualized under UV and photographed using the DigiGenius gel documentation system, Syngene.

RESULTS

Initially, the PCR amplification of BRCA1 exon 5 was performed for all samples using the same DNA amount, based on the provided concentration information. The required assay DNA input amount was 50ug. Unfortunately, the results of this first attempt were far from satisfactory. We obtained for all the 120 samples analyzed only 64 (53%) visible bands but just 42 (35%) of the expected size and without contaminations. The best results was obtained for BC controls extracted from blood tissue, 69% of which has visible bands, and the worst was for the PC patients DNA extracted from blood tissue, where only 31% of samples shown acceptable amplified bands.

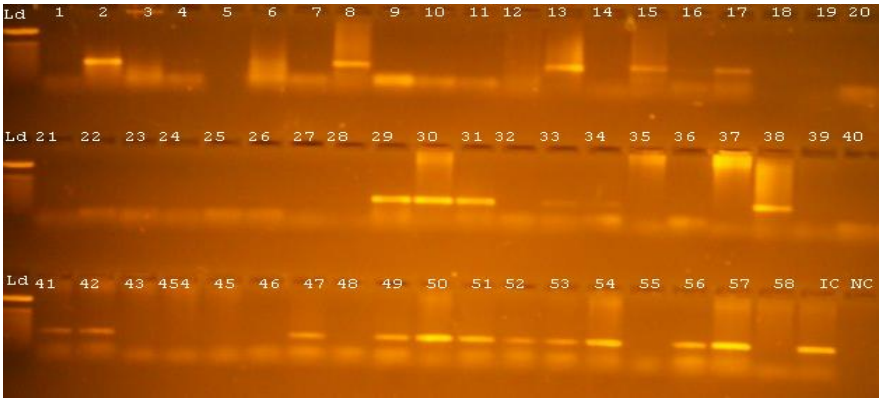

Fig. 1. PCR analysis of BRCA1 exon 5 regions 1.5% agarose gel electrophoresis of the PCR products to verify the correct amplification. Ld: molecular weight marker. IC: internal control DNA- a sample with known 50ng amount in reaction mixture. NC: negative control. Each lane corresponds to the amplicon relative to the DNA extracted from different sample

In attempt to elucidate the cause of such poor PCR amplification results we decide to remeasure the concentration and the quality of DNA using the spectrophotometer and the optical density (OD) ratio at 260 nm / 280 nm. We got a highly variated pattern of value ranged from very low concentration and DNA quality to pretty high value (tab. I). Only about half of them was more than 50 ng/μL concentration and with 260 nm / 280 nm ratio ranged between 1.8 and 2.

As we were unable to have the DNA at the recommended input concentration for a high proportion sample, we increased the input DNA volume. Samples was processed with a series of input DNA amounts from the recommended 1μL of DNA for samples that could be diluted to 50ng/μL to 2 or even 3 μL of DNA for these lower than 50ng. This variable volume was used for more than 50% of our sample set. In accordance to the new DNA concentration value we adjust the DNA amount added to reaction mix to be 50 ng - the same for the all samples. This time we obtained more uniform results, 82% of the samples has exon 5 amplified, but the bands intensity was very low for most amplicons (fig. 2).

TABLE I.
Summary of BRCA1 exon 5 amplification results after initial analysis and on remeasured samples

Samples	Sample number	DNA concentration ng/µL	R260/280 ratio	Before remeasuring		After remeasuring	
				Average efficiency amplification	Good efficiency amplification	Average efficiency amplification	Good efficiency amplification
BC blood	38	18-452	1.142-1.889	21	14	31	26
BC control	39	18-162	1.467-1.938	27	19	34	31
PC blood	32	14-430	1.309-1.998	10	6	27	22
PC control	11	15-501	1.556-1.882	6	3	7	6
Total	120	14-501	1.142-1.998	64	42	99	85

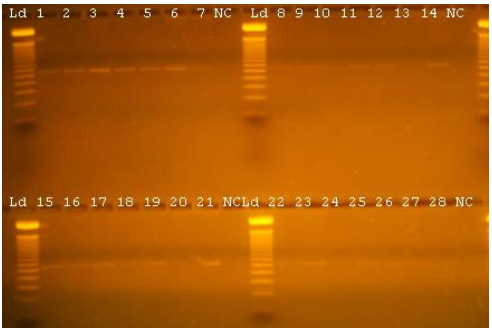

Fig. 2. PCR analysis of BRCA1 exon 5 regions after remeasuring of the DNA samples. 1.5 % agarose gel, Ld: molecular weight marker. IC: internal control DNA- a sample with known 50ng amount in reaction mixture. NC: non-template control. Each lane corresponds to the amplicon relative to the DNA extracted from different sample

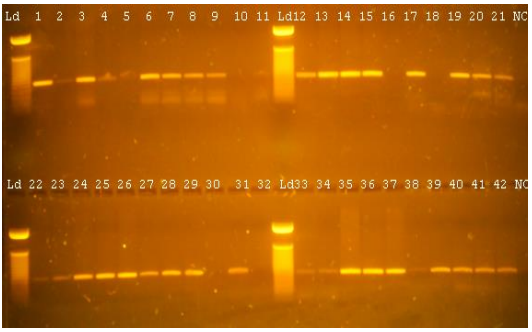

Fig. 3. PCR analysis of BRCA1 exon 5 regions with increased amount of DNA from 50 to 100ng per reaction mixture. 1.5 % agarose gel, Ld: molecular weight marker. IC: internal control DNA- a sample with known 100 ng amount. NC: non-template control. Each lane corresponds to the amplicon relative to the DNA extracted from different sample

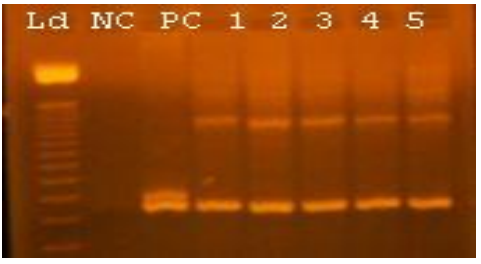

Fig. 4. Electrophoretic profiles of multiplex-PCR products issued from a 20 µL amplification volume, in 3% agarose gel Ld: DNA 50 bp step ladder; NC: No template control; PC: Positive 5382insC DNA control amplification; Lanes 1-5: BC patients DNA amplifications

We decided to increase the DNA impute amount from 50 to 100 ng per reaction mix and the band intensity increased to a satisfactory level (fig. 3). At least for breast cancer samples more than 90% of amplicons had bands with expected size, good intensity and without contaminations. We repeated the PCR amplification for the samples without clear bands to ensure that all working errors were excluded. The percent of samples with satisfactory bands increase from 90 to 95%.

Once all the amplicons covering the exon 5 BRCA1 were obtained, we chose a 3 primers multiplex-PCR method previously described (fig. 4**)** to detect the BRCA1 exon5 5382insC mutation on several BC samples from our collection. Method require a good quality of DNA samples so it would be a good way to confirm the validity of our results and the good start for further experiments on the DNA collection. The results have shown a simultaneous amplification of the control and the wild-type specific products, generating in this way a functional multiplex-PCR for several BC DNA samples and confirmed the good quality of provided samples.

DISCUSSION

Most of the methods for mutation analysis currently available rely on polymerase chain reaction (PCR) amplification of the target DNA. Unfortunately, PCR is more difficult with DNA of less-than-optimal quality and concentration. Low amounts of DNA samples are associated with decreased PCR yields and a progressive inability to amplify longer templates (16). Beside concentration the relative difficulty of producing PCR products is often related to DNA due to damage both from extraction process or preservation. Damage at even a single base can block polymerase elongation and destroy the template. However, DNA is a complex molecule, and it has been difficult to distingue between quantity and quality when it is about the PCR efficiency, especially because damage is likely to be randomly distributed or different between templates (17). Although to a lesser extent, the impact of other PCR components such as salt, dNTPs, oligonucleotide primers, as well as the effect of regionally stable secondary structures of DNA template on the productivity of PCR amplification have also been studied (18).

In theory, a single copy of DNA or a single cell is sufficient for amplification by PCR under ideal conditions. In practice, however, amplification efficiency of a specific template amount is highly dependent upon reaction components and parameters, as well as sensitivity of the DNA polymerase. In the present study, we show that very low concentration of DNA template in PCR mix less than 30ng can lead to low DNA template concentration-dependent production. Benita and co-workers (19) in an extensive study of factors influencing PCR success demonstrated that the template rather than the primer was most often the cause of PCR failure.

CONCLUSIONS

We concluded primarily that DNA extracted from different tissue by different extraction methods may be damaged but still readable by increasing the DNA amount in the PCR mix and adjust the other PCR components. However, appropriate caution should be exercised when analyzing small numbers of templates or DNA

derived from different tissue sources. These conclusions could improve our ability to provide PCR conditions equally favorable for amplification of all templates in complex samples.

CONFLICT OF INTEREST

The authors declare that there is no conflict of interest. The author Sara Y. Houngues received the *Eugen IONESCU* scholarship from the Romanian State, the Agence Universitaire Francophone (AUF) Notification no. 9006/20.04.2022.

ACKNOWLEDGMENTS

We would like to thank the Agence Universitaire Francophone (AUF), who granted us the *Eugen IONESCU* scholarship from the Romanian State. This article was written in the framework of this grant.

NEWS

EVALUATION ON THE CORROSION RESISTANCE, ANTIBACTERIAL PROPERTY AND OSTEOGENIC ACTIVITY OF A NEW BIODEGRADABLE MG ALLOYS

the last decade, being seen as a viable alternative to osteofixation systems with biomaterials like Co-Cr, stainless steels and titanium in view of their use in the dental, alveolar and maxillofacial field. The orientation towards the third category of biomaterials, which also includes biodegradable Mg-based materials, is given by the fact that no new surgery is required to remove osteofixation systems, they have good biocompatibility, with mechanical properties and the modulus of elasticity similar to cortical bone, high capacity for osseointegration and could have the corrosion rate close to the healing rate of bone tissue. The rapid degradation of magnesium (Mg)-based implants in physiological environment limits its clinical applications, and alloying treatment is an effective way to regulate the degradation rate of Mg-based materials. In this work we aimed to obtain a new alloy based on Mg-Ca-Zn-Ag for which we performed *in vitro* and *in vivo* tests. The results showed that after alloying Mg with Ca the Mg-based alloy has a corrosion rate compared to the bone recovery period and after addition of Zn and Ag, the antibacterial potential of Mg alloys was also enhanced. After implantation in a rat femoral showed significantly osteogenic activity and bone substitution rate due to its higher corrosion resistance as well as the stimulatory effects of the released metallic ions. The current work not only evaluated the clinical potential of the biodegradable Mg alloys as bone grafts but also provided a feasible approach for predicting the in vivo degradation behavior of biodegradable materials. (Hewei C, Yuan B, Zhao R, *et al*. Evaluation on the corrosion resistance, antibacterial property and osteogenic activity of biodegradable Mg-Ca and Mg-Ca-Zn-Ag alloys *Journal of Magnesium and Alloys* / doi.org/10.1016/j.jma.2021.05.013).

110 YEARS SINCE THE BIRTH OF CONSTANTIN ARSENI–THE FOUNDER OF ROMANIAN NEUROSURGERY (Abstract): The history of Romanian neurosurgery and the evolution of ideas in this field are inextricably linked to the evolution of the brain chronography process in its complexity. This process, which has shown an uneven but ascending evolution, in terms of morphology, function and their implications in medical practice, in the spiritual and material life of man, continues today. Neurosurgery is the frontier specialty with Neurology, Ophthalmology, Otolaryngology and Maxillofacial surgery, which has managed to snatch from each of these chapters of pathology, exploration methods and surgical approach, creating its own methods of exploration and diagnosis, technique and specific operator instrumentation, which led to the formation of his own personality. The authors will present one of the great personalities of Romanian neurosurgery, Dr. Constantin Arseni, the descendant of Prof. Dr. Dumitru Bagdasar, who founded it in Bucharest, creating the largest university center of neurosurgery in Europe at that time (1975). **Keywords:** HISTORY, NEUROSURGERY, FOUNDER, DUMITRU BAGDASAR, CONSTANTIN ARSENI.

In Romania, Neurosurgery developed as a separate specialty starting in 1932. Until then neurosurgical activity was sporadically, represented by operations on the nervous system performed by the great surgeons of the time in Romania. Some of the operations were, however, outstanding for a period in which anesthesia and resuscitation techniques in the postoperative phase were insufficient, and rehabilitation hardly known. In 1895, Dr. Bardescu was the first in the world to perform a resection of Gasser's ganglion for trigeminal neuralgia, operation he also repeated in 1902.

Subsequently, other Romanian surgeons – Toma Ionescu, Amza Jianu, Iancu Jianu, Iacob Iacobovici – carried out surgery for the removal of brain tumors, and Leonte operated on the spinal cord for tumoral compression or applied antero-lateral cor-

dotomy in cases of refractomy pains. It is certain that these Romanian surgeons, preoccupied by the management of nervous lesions, were stimulated by their cases, imposed the Romanian School of Neurology at International level. The anatomical, physiologic and clinical investigations of Gheorghe Marinescu, Minea, Noica, Radovici, Paulian, Danielopolu, I. T. Niculescu and others represented this stimulus promoting ideas and therapeutical methods diseases of the brain and spinal cord.

In Iasi, Prof. Dr. Alexandru Moruzzi (1900-1957) is a key Romanian Medical Personality who was formed by the French School of Medicine. After completing his studied in Paris under the first Neurosurgeon Thierry de Martel (1875-1940), he worked in Romania as a General Surgeon in Prof. Amza Jianu's Clinic at Charity Hospital in Iasi. In 1933, with help of Prof. Leon Ballif (1892-1967) Prof. Moruzzi creates the first department of neurosurgery in Romania at Socola Psychiatry Hospital in Iasi (the third psychiatry hospital in Europe after Stockholm and St. Petersburg).

If we talk about the Bucharest Universitary Center, Prof. Dr. Dumitru Bagdasar (1893-1946) is considered the founder of the Romanian School of Neurosurgery. He is direct student at Prof. Harvey Cushing School of Neurosurgery (1926-1931). His activity in Boston was greatly appreciated by his mentor, being regarded as Cushing's Honorary Assistant.

In 1929, after returning from the United States of America and considering Romania did not yet recognize neurosurgery as an independent surgical specialty, he was employed as a neurologist by Jimbolia Neuropsychiatric Hospital. In 1931 is promoted to chief of Neurology Department at Cernauti Hospital. From 1929 to 1934 he performed over 200 surgical inventions on neurosurgical pathologies. After numerous pressures, in 1935 he succeeds in establishing the first independent neurosurgical department in Bucharest Central Hospital of Nervous Disease – the second as a national scale, after Socola Psychiatry Hospital in Iasi. After his death, Prof. Constantin Arseni continued the devoted activity of Prof. Bagdasar, being considered as the founder of the Romanian School of Neurosurgery (1, 2).

EARLY LIFE AND EDUCATION

Dr. Constantin Arseni was born in Dolhasca Commune, Suceava County, on February 3rd, 1912 (fig. 1). He attended primary school in Dorohoi. After graduating from Bacau High School, he enrolled at the Faculty of Medicine and Pharmacy in Cluj-Napoca, where he distinguished himself as an eminent student and graduated in 1935 as head of promotion. As a student, he had the chance to hear elite professors of Romanian medicine: Prof. Iacob Iacobovici (1879-1959) - General Surgery, Prof. Iuliu Hatieganu (1885-1959) - Internal Medicine, Prof. Victor Papilian (1888-1956) - Anatomy, Prof. Grigoriu Cristea (1883-1951) - Obstetrics-Gynecology.

Fig. 1. Prof. Dr. Constantin Arseni (1912-1994)

On June 30th, 1936, he presented his doctoral thesis entitled *"Juxtaprotuberential Neuroanatomy in the treatment of Trigemen's Neuralgia* being a premiere in Romania, as until then no theses with Neurosurgical titles had been approached, the subject arousing the attention of great professors (fig. 2).

Dedicating his life to medicine, the young Constantin Arseni quickly promoted and entered medical education as a University Assistant at the Department of Pathological Anatomy, led by Professor I. T. Niculescu (1895-1957) (3).

A NEW LIFE AS A NEUROSURGEON

Pursuing a career in the operating room, he worked for three years at the Emergency Hospital in Bucharest, where he sharpened his talent as a surgeon, after which he will work with Prof. Dr. Dumitru Bagdasar, helping to raise the foundations of Romanian Neurosurgery (fig. 3).

Fig. 3. Prof. Dr. Dumitru Bagdasar (1893-1946)

After the tragic loss of his mentor Prof. Dr. Dumitru Bagdasar in 1946, Dr. Constantin Arseni, a 34-year-old primary care physician, took over the management of the neurosurgery service at the Central Hospital for Mental, Nervous and Endocrinologic Diseases, the only department of this kind in this country. After taking up duty in 1946, in the Department with 80 beds and after strenuous endeavors, Constantin Arseni was able to have the first Clinic of Neurosurgery from Romania (4).

He operated in difficult conditions, together with Dr. Ionescu Ion, Dr. Sofia Ionescu-Ogrezeanu with carpeted gloves,

reduced medical staff and emergency avalanches (fig. 4).

He had at his disposal a single Boovie electrocoagulation device brought by Prof. Dr. Dumitru Bagdasar from the United States of America. The radiological examination was performed in the radiology service located at a distance from the clinic, the patients being transported at that time with a stretcher.

The need to practice new techniques involved conducting numerous studies in the autopsy room. Following a totally unpleasant incident, Dr. Constantin Arseni contracted sepsis and was extremely rescued by the risky penicillin obtained from the American Embassy.

The multitude and difficulty of the cases, the small number of collaborators (Dr. I. Ionescu, Dr. V. Miclaus, Dr. T. Iacob and Dr. S. Ionescu) imposed a spartan work schedule.

Dr. Constantin Arseni was in the hospital at 5 o'clock in the morning, even on Saturdays, to deal with this program. The examination of the patients and the operating program ended in the afternoon, but Dr. Arseni continued his activity until late in the evening (consultations, follow-up of operated patients, scientific activity) (5).

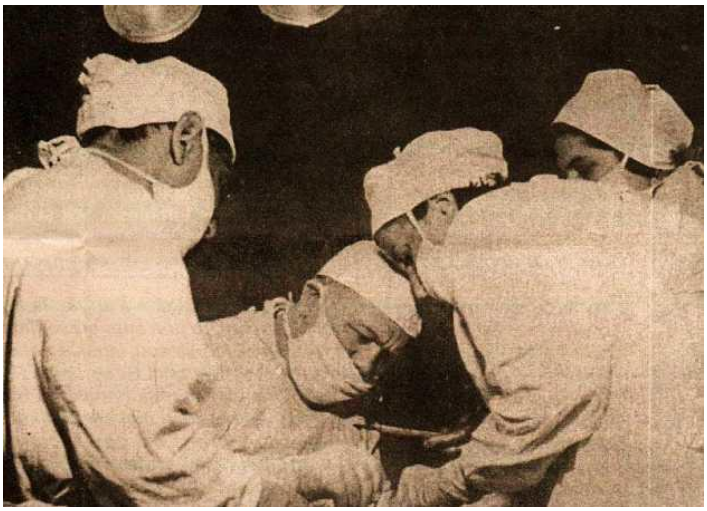

Fig. 4. Prof. Dr. Constantin Arseni and Dr. Sofia Ionescu in the surgery theatre

"FATHER" OF ROMANIAN NEUROSURGERY

For his merits, Dr. Constantin Arseni, became an Associate Professor in 1952 and University Professor of "Carol Davila" University of Medicine and Pharmacy in 1963.

As a result of this activity, the prestige of the clinic increases with the confidence in this specialty, the patients no longer being directed in outdated stages. Under these conditions, through the intervention of Professor Constantin Arseni, the hospitalization capacity reaches 220 beds, often being exceeded.

The Clinic of Neurosurgery of Bucharest developed rapidly, approaching the most varied aspect of neurosurgical pathology. The increased number of subjects with which the Clinic was concerned ne-

cessitated a constant effort of organization, technical development and research work. In 1964 the number of beds had increased to 220, distributed in the various sections strictly according to the specialties: two surgical sections for cerebral expanding processes, one each for vertebro-medullary surgery, infantile neurosurgery, cerebro-vascular surgery, epilepsy and dyskinesia, head and spinal injuries, with a subsection of general traumatology. There are two operative blocks with 7 operation theaters. In 1960 a special anesthesia and intensive care unit was opened and equipped according to the most modern requirements.

Paraclinical activity and scientific research was carried out at that time (1964) by a laboratory of electroencephalography with 4 modern apparatus, a laboratory of electro-myography, of neuromorphopathology and biochemistry.

The neuroradiology department developed both in the direction of standard investigations and complex research work with contrast media: angiography, ventriculography, iodoventriculography, air and iodine ventriculography. The surgery of epilepsy may be applied owing to a stereotaxic surgical equipment.

Under Professor C. Arseni, the Neurosurgical Clinic of Bucharest is transformed in 1975 into the "Prof. Dr. D. Bagdasar" Clinical Hospital of Neurosurgery, the largest hospital of Neurosurgery in the Europe, with 550 beds and, subsequently, 650 beds (fig. 5).

It appears as a crowing and a confirmation of the value of Neurosurgery withing the framework of medical specialties (5).

This passion for the study of the morpho pathology of the central nervous system materialized in the realization of an important collection of Anatomo-Pathological pieces specific to various intracranial expansive processes and especially of brain tumors, whose biology has preoccupied him all his life (fig. 6).

Fig. 5. Neurosurgical Clinic "Prof. D. Bagdasar" opened in 1975 with all the facilities.

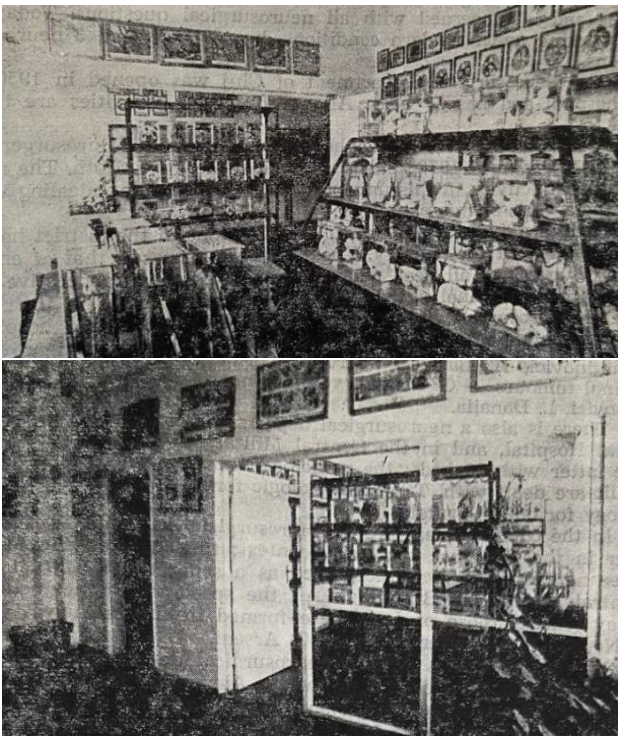

Fig. 6. Museum of Anatomo-Pathological nervous system pieces

SCIENTIFIC ACTIVITY DURING NEUROSURGERY

Scientific activity of Prof. Dr. Constantin Arseni includes the numerous publications, especially those of the cases of Clinic of Neurosurgery from Bucharest. These articles were designed to inform the medical staff in general concerning neurosurgical diseases and to obtain early and competent diagnosis. Among the most interesting publications, some of which have become classical are: "Vertebral sciatica" (1948), "Vascular Diseases of The Brain and Spinal Cord" (1965), "Neuro-ophthalmologic Diagnosis" (1967), "Raised Intracranial Pressure" (1972), "Pathologic Anatomy of Tumors of the Central Nervous System" (1978), "Cerebrospinal Fluid" (1979).

In the domain of pediatric neurosurgery, a self-standing specialty since 1960, the following reference publications were published: "Problems of Neurosurgical Diagnosis in Infantile Pathology" (1978), "Neurosurgical Diseases in Infants and Young Children" (1979), "Infantile Neurosurgical Pathology" (1980) by the cooperation of the teams under C. Arseni, Lenke Horvarth and A. V. Ciurea, on the basis of their experience gained in the Department of Pediatric Neurosurgery.

With the contributions of the entire Clinic of Neurosurgery in the various spheres of this specialty 19 monographs were edited under Prof. Dr. C. Arseni.

An editorial board under C. Arseni published, with the substantial contribution of the medical staff of the Clinic, the "Treatise of Neurology" in 8 volumes, during 1979-1981 period.

The great number of publications are

due not only the constant, assiduous work of the medical staff but also to the numerous up-to-date books (about 7,000) and journals (218 titles) in the library of the Clinic (fig. 7).

Similar, the archives, listed in alphabetical order of subjects are the files of the case cards (150,000) since 1935 and up to date.

The Neurosurgical departments throughout the country have a vast scientific activity, with numerous communications and papers published at home and abroad. The more than 350 specialty publications of Prof. Constantin Arseni are known throughout the world and represent the references on subjects such as tumors on the brain, tuberculomas, parasitic diseases of the nervous system, abscesses of the brain, epilepsy and craniocerebral neuro-traumatology(6).

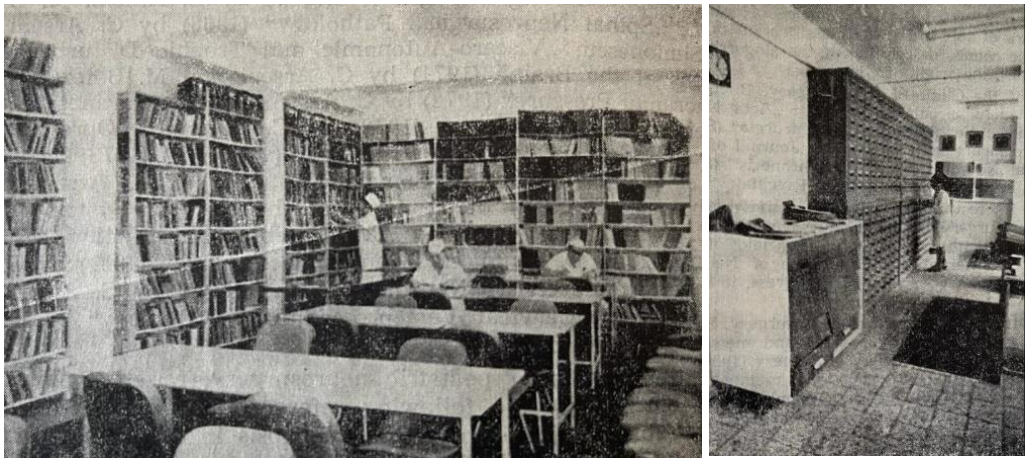

Fig. 7. The Library and the archives files of "Prof. Dr. Bagdasar" Clinical Hospital

RECOGNITION

For his activity in the domain of neurosurgery, Professor C. Arseni has been awarded with numerous titles and membership: Member of International Society of Surgery (1956), Member of the World of Federation of Neurology (1957), Honorary Member of the French Society of Neurosurgery (1959), Member of the Academy of Sciences of New York (1964), Corresponding Member of the R.S.R. Academy (1974), etc.

Along social lines, Prof. C. Arseni was distinguished with medals, orders and prizes for his outstanding merits: The "Victor Babes" prize of the R.S.R. Academy in 1972; the "Meritul Sanitar" in 1970. For his social and professional activity in the field of neurosurgery for more than 45 years, Prof. C. Arseni was elected as Honorary Member of Romanian Academy *post-mortem*.

CONCLUSIONS

Professor Constantin Arseni was a dedicated surgeon, he practiced his job asking from those around him as much as he offered - the maximum. He was a schoolmaster and a teacher in the true sense of the word. Although criticized for his didactic extremism and the pretensions he raises from the aspirations of the title of "Neurosurgeon", Professor Constantin Arseni teaches neurosurgery "in the hard way", in an exhaustive and elitist way. Most of the

heads of the neurosurgical departments in the country are former students of his. As a sign of gratitude for the contributions made to the health of the Romanian people, C. Arseni was elected Member of the Romanian Academy in 1980 and President of the Academy of Medical Sciences in 1984.

Professor Constantin Arseni was an exemplary professional, a model of conduct, which will forever remain in our memory, of the neurosurgeons, and of the Romanian neurosurgery, leaving behind a legacy hard to match for those who followed him.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

FACTORS THAT INFLUENCE THE DESIRE TO AVOID A NEW PREGNANCY. A SINGLE CENTER STUDY **(**Abstract). The **aim** of the study was to identify the factors that are related to the women's desire to avoid a new pregnancy. **Material and methods**: A total of 197 mothers were questioned about the pregnancy after giving birth, and the study collected data about their sexual-related lives, the satisfaction with their relationship with partners and medical team, peripartum aspects, and their desire to have a new pregnancy in the next period, using *the Desire to Avoid Pregnancy Scale* (DAP), a psychometric scale. The analysis of the data was done using the SPSS program, version 24. **Results**: The analysis of the data revealed that women declared that they were mostly satisfied with the relationships they had with their gynecologists (M = 5.46 ± 1.59), the medical care they received from the nurses (M = 5.49 ± 1.43), the hospitalization conditions (M = 6.05 ± 1.26), the hospital food (M = 5.86 ± 1.33), and the provision of medical equipment in the hospital (M = 6.04 ± 1.11). The DAP subscales revealed the following results: *Cognitive Desire and Preferences* - M = 20.26 ± 3.79; *Affective Feelings and Attitudes* - M = 10.47 ± 3.56; and *Anticipated Practical Consequences* - M = 7.93 ± 3.22 for a total DAP score of about M = 37.56 ± 10.75 with scores ranging from 13 (0.6%, N = 1) to 56 (2.3%, N = 4). Married women had a significantly lower score on the DAP scale, both compared to women who lived in cohabitation and compared to those who no longer maintained a relationship with the child's father. More results were obtained considering the variables age at first sexual contact, level of education, marital status, intended or unintended pregnancy, and satisfaction with medical care during pregnancy. **Conclusions**: There are a lot of factors that influence the desire of women to avoid a new pregnancy, and ob-gyn doctors and psychologists should take them into consideration when medical care is provided to mothers who have a pregnancy within a short time after giving birth. **Keywords**: PREGNANCY, THE DESIRE TO AVOID PREGNANCY SCALE, ROMANIA, TEENAGE PREGNANCY, SINGLE MOTHER, SATISFACTION WITH PREGNANCY, PAIN SCALE.

The birth rate for 2023 was about 17,464 births per 1,000 people, a 1.15% decline from 2022, and worldwide, fertility fell from an average of 5 births per woman in 1950 to 2.3 births per woman in 2021, with an increased rate in poor countries (1).

More than half of pregnancies are unintended, and some trends can be identified in diverse countries: high rates of pregnancies among teenagers, an increase in the pregnancy rate among women older than 40, the desire to have children after reaching educational and financial stability, children born in a single-parent family (2, 3).

There are a lot of factors that influence the desire of women to have or not have children: the family model, the image of women in the cultural group, the influence of peers, the level of education, the marital status, the medical or sexual education, the type of family, the consumption of drugs, the financial status, the involvement in risky sexual behavior (4-7). Cultural norms related to pregnancy and reproduction can be determined by a variety of values and could be addressed through education about a responsible, healthy sex life, family planning, and emphasizing sexual behavior within marriage. In some cultures, pregnancies resulting out of wedlock may be considered immoral, causing social pressure, while in others, conceiving a child may be considered a cultural responsibility. Depending on a woman's status in a culture, the decision about pregnancy or appropriate family planning can be determined (8).

The quality of sex education is one of the educational factors involved in the incidence of pregnancies. The more this education includes complex information related to notions of anatomy, physiology, sexuality, contraceptive methods, or family planning, the more the ability to make responsible decisions is increased. Education plays an important role in accessing medical services. Research shows that achieving high levels of education discourages teenage pregnancy (9).

Socio-economic factors can contribute to the incidence of pregnancy in adults and minors through the level of education. The higher this is, the greater the ability to make responsible family planning decisions. A limited or increased level of financial resources can contribute to access to medical monitoring and reproductive health services. Socio-economic factors can amplify each other, resulting in a lower or higher incidence of pregnancies depending on them (10, 11).

Additionally, the impact of religious factors on the desire to have children has significant echoes in general, but predominantly on women. The diversity of religious communities can significantly impact this aspect, and the factors that influence this decision can also be diverse. One of them referred to the specific rules of a religious doctrine regarding the onset of sexual life, sexuality, contraception, and family planning. Another aspect is the promotion of patriarchy, where women have a limited role in deciding whether to get pregnant or how many members of a family they have (12). The absence of sex education as determined by religious rules is another factor that affects the decision to get pregnant (13). The occurrence of pregnancies can also be influenced by social pressure on women and couples to have children or by restricting access to family planning and contraception services (14).

The aim of the present study was to identify the factors that are related to the desire to avoid pregnancy in women.

MATERIAL AND METHODS

Participants and data collection

The study was conducted between May 1st-15th, 2023, and the questionnaires were distributed to women hospitalized at the

"Cuza-Voda" Maternity Hospital in Iasi, Romania, after they gave birth. The participants were informed about the purpose of the study, about the fact that they could withdraw from the study whenever they wanted, without consequences, and about the confidentiality of the data. No incentive was given to respondents. The inclusion criteria were confinement after birth and filling out the questionnaire before the deadline. The exclusion criteria were questionnaires that were incomplete or submitted after the deadline. Finally, 179 questionnaires were included in the research.

The online questionnaire was created using the Google Forms application (Alphabet, Mountain View, CA, USA) and was developed to obtain detailed information about satisfaction with everything related to the act of giving birth and the desire to become pregnant.

a. The first part of the questionnaire gathered socio-demographic information (such as age, marital status, living environment, level of studies, number of children, and if they had a stable job).

b. The second part collected information about sex life and pregnancy (at what age the first sexual contact took place, how old they were when they got pregnant for the first time, if there were any miscarriages), as well as detailed information about the current pregnancy (the way they got pregnant, if the pregnancy was planned and wanted, if it was felt as difficult, the type of pregnancy, how many months of pregnancy they had when they consulted the gynecologist, and if the gynecologist counseled them during the pregnancy, the type of birth and if it was considered to be difficult, if they were assisted by a doctor during the birth, and if they were consulted by a psychologist).

c. The third part of the survey aimed at the satisfaction of women who had just given birth with regard to the relationship with their gynecologists from all points of view (communication, how to explain the medical situation, medical care, emotional support, and the time given during consultations). It also aimed at these women's satisfaction regarding different aspects related to the communication of the patients with the nurses and the midwives in the hospital, the medical care received, the conditions of hospitalization, the conditions in the delivery room, the food received, and the provision of medical equipment in the hospital. Furthermore, the participants were asked how they appreciated the attitude of the gynecologist towards them and the extent to which they believed that the gynecologist considered all the aspects presented by the patient. In this section, questions were asked about the degree of women's satisfaction regarding the relationship with the family and the child's father, but also related to the lives they led both during pregnancy and before becoming mothers for the first time.

d. The final part of the questionnaire included one psychological tool - *the Desire to Avoid Pregnancy Scale* (DAP), which is a psychometrically validated measure of pregnancy preferences that was developed in the USA in 2019 (15, 16). The DAP scale covers three conceptual domains: (1) cognitive desires and preferences; (2) affective feelings and attitudes; and (3) anticipated practical consequences. Each item uses a Likert scale, scored 0–4, to ask women how much they agreed or disagreed with a statement about either becoming pregnant in the next 3 months or having a baby in the next year. The re-

sponses were averaged, and a higher score represents a higher DAP (16). The DAP scale showed good reliability, with a Cronbach's α of 0.95 (15, 16).

Statistical analysis

The statistical analyses were performed using *IBM Statistical Package for Social Sciences* (SPSS) for Windows, *version 24* (SPSS Inc., Chicago, IL, USA). The results for descriptive statistics were expressed as means and standard deviations (SD).

The normality of the data distribution was assessed using the Kolmogorov-Smirnoff test. Given the fact that all data are not normally distributed, a bivariate analysis will be performed, and non-parametric tests will be applied. To assess comparative results considering planning and wanting a pregnancy, the way to stay pregnant, the way to give birth to the child, and performing medical tests during the pregnancy, the Mann-Whitney test was performed.

The comparative results considering marital status were assessed using the Kruskal-Wallis H test to determine if there were statistically significant differences between more than two groups of an independent variable on a continuous or ordinal dependent variable.

The Spearman correlation was used to test the relationship between variables. A p-value < 0.05 was considered statistically significant.

Ethical approval

The study was conducted in accordance with the Declaration of Helsinki, and the protocol was approved by the Ethical Committee No. 5035/21.04.2023 of "Cuza-Vodă" Obstetrics and Gynecology Hospital, Iasi, Romania.

RESULTS

Socio-demographic data

The women in the study were, on average, M = 28.43 ± 7.50 old (with a minimum of 13 and a maximum of 53 years old). More than half of them came from urban areas (55.5%, N = 96).

The participants of the study had a good level of education, less than half of them had completed university studies (44.5%, N = 77), and approximately one third of them had high school education (27.2%, N = 47). More than half of the women in the present study had a stable job (63.6%, N = 110).

Most of the participants were married (74.6%, N = 129), and less than half of the women had given birth to their first child (45.1%, N = 78). More than a third of the women declared that they had a second birth (33.5%, N = 58), while the rest declared that they still had two (14.5%, N = 25), three (2.3%, N = 4), four (1.7%, N = 3), five (2.3%, N = 4), or six or more children at home (0.6%, N = 1).

Information about sexual life, pregnancy, and birth

The average age at which women had their first sexual contact was M = 17.84 ± 3.27. The average age at which women became pregnant for the first time was M = 23.98 ± 5.93, the youngest mothers being 12 years old (1.2%, N = 2), and the oldest being 41 years old (0.6%, N=1). Less than a third of the women declared that they had miscarriages (27.7%, N = 48).

Regarding the current pregnancy, more than a third of the women did not plan to become pregnant (39.3%, N = 68). Most of the women in the present study got pregnant naturally (91.3%, N = 158), and a small part of them resorted to in vitro ferti-

lization (8.7%, N = 15). Additionally, most of the women had a single pregnancy (93.1%, N = 161), with a few of them having a twin pregnancy (5.8%, N = 10) or even a multiple pregnancy (1.2%, N = 2).

The number of months of pregnancy at which women consulted a gynecologist was on average M = 2.87 ± 2.25. Most of the women in this study considered that they did not have a difficult pregnancy (78.0%, N = 135); instead, almost half declared that the birth was difficult (43.9%, N = 76), approximately one third of the women (28.3%, N = 49) stating that the pain felt throughout the birth and immediately after the birth was the greatest pain they had experienced. More than half of the women were consulted by a psychologist after birth (52.0%, N = 90).

Most of the women (96.0%, N = 166) were assisted by a doctor at birth, and a little more than half of them gave birth naturally (50.9%, N = 88). On average, the Apgar score obtained by the newborns was M = 8.38 ± 1.41.

Satisfaction regarding the doctor-patient relationship, the relationship with the medical staff, and the family

More than half of the women (64.2%, N = 111) who participated in the study declared that they were treated with respect by their gynecologist. Furthermore, more than half of the patients were very satisfied with the conditions in the delivery room (53.2%, N = 92). More than a third (36.4%, N = 63) said that the gynecologist considered all the aspects presented by the patients to a large extent.

On a scale from 1 (*very dissatisfied*) to 7 (*very satisfied*), women were mostly satisfied with the relationship they had with the gynecologist, the average being M = 5.46 ± 1.59. Similarly, women were even more satisfied with the medical care they received from the midwives (M = 5.49 ± 1.43), the hospitalization conditions (M = 6.05 ± 1.26), the hospital food (M = 5.86 ± 1.33), and the provision of medical equipment in the hospital (M = 6.04 ± 1.11). Other detailed results are presented in first table.

TABLE I.

Self-rated items regarding satisfaction with the doctor-patient relationship and the relationship with the medical staff *

How satisfied are you with …	1	2	3	4	5	6	7	M ± SD
the relationship with the gynecologist in the hospital?	1 (0.6)	4 (2.3)	16 (9.2)	40 (23.1)	19 (11.0)	19 (11.0)	74 (42.8)	5.46 ± 1.59
the time the gynecologist at the hospital allotted you during the consultations?	3 (1.7)	24 (13.9)	27 (15.6)	17 (9.8)	11 (6.4)	21 (12.1)	70 (40.5)	5.03 ± 2.00
the communication with the gynecologist in the hospital?	6 (3.5)	23 (13.3)	30 (17.3)	14 (8.1)	10 (5.8)	23 (13.3)	67 (38.7)	4.94 ± 2.05
the way in which the gynecologist clearly explained the details related to the medical situation?	7 (4.0)	29 (16.8)	22 (12.7)	13 (7.5)	9 (5.2)	21 (12.1)	72 (41.6)	4.96 ± 2.13
the medical care that the gynecologist in the hospital gave?	2 (1.2)	11 (6.4)	16 (9.2)	37 (21.4)	16 (9.2)	19 (11.0)	72 (41.6)	5.31 ± 1.74
the emotional support that the gynecologist in the hospital gave you?	41 (23.7)	22 (12.7)	11 (6.4)	8 (4.6)	10 (5.8)	15 (8.7)	66 (38.2)	4.35 ± 2.54
the medical care that the nurses in the hospital gave you?	2 (1.2)	2 (1.2)	9 (5.2)	34 (19.7)	37 (21.4)	27 (15.6)	62 (35.8)	5.49 ± 1.43

How satisfied are you with …	1	2	3	4	5	6	7	M ± SD
the communication with the nurses in the hospital?	1 (0.6)	2 (1.2)	20 (11.6)	41 (23.7)	26 (15.0)	22 (12.7)	61 (35.3)	5.31 ± 1.53
the communication with the midwives in the hospital?	2 (1.2)	11 (6.4)	19 (11.0)	27 (15.6)	24 (13.9)	29 (16.8)	61 (35.3)	5.26 ± 1.69
the medical care you received during your hospitalization?	-	5 (2.9)	8 (4.6)	37 (21.4)	29 (16.8)	27 (15.6)	67 (38.7)	5.54 ± 1.44

* Number of answers (N) and percentage (%), means and standard deviations (M±SD)

Regarding the relationships with family members, around half of the participants declared that they were very satisfied, both with the relationship they had with the children's fathers (52.0%, N = 90), and with the relationships with the families (48.6%, N = 84), the average being M = 5.93 ± 142, respectively M = 5.80 ± 1.52. In terms of their lives before becoming mothers for the first time (M = 5.79 ± 1.44) and during pregnancy (M = 5.66 ± 3.38), women's satisfaction with life as a woman was slightly lower.

Desire to Avoid Pregnancy Scale (DAP)

The Cronbach Alpha score was 0.93 for the total scale, 0.87 for Domain 1 – Cognitive Desire and Preferences, 0.86 for Domain 2 - Affective Feelings and Attitudes and 0.74 for Domain 3 - Anticipated Practical Consequences.

For these DAP subscales, we obtained the following results: *Cognitive Desire and Preferences* - M = 20.26 ± 3.79, *Affective Feelings and Attitudes* - M = 10.47 ± 3.56 and *Anticipated Practical Consequences* - M = 7.93 ± 3.22.

The total DAP score was on average M = 37.56 ± 10.75, scores ranging from 13 (0.6%, N = 1) to 56 (2.3%, N = 4).

Comparative and correlational analysis

A Mann-Whitney U test was run to determine if there were differences in the DAP total score between women who planned the pregnancy and wanted to be pregnant and those who didn't. The DAP total score was statistically significantly higher in women who did not want the pregnancy (Mdn = 42.00) than in women who wanted to be pregnant (Mdn = 32.00), ($p < 0.01$, U = 829.00, z = - 4.080).

The comparative analysis also showed that there were differences in the DAP score, in the variable that refers to the way that women got pregnant ($p = 0.043$, U = 195.00, z = -2.028), in the sense that women who got pregnant naturally had a higher score on this scale (Mdn = 38.00) than women who got pregnant through in vitro fertilization (Mdn = 27.00).

The results showed that there was a significant difference regarding the score obtained on the *Desire to Avoid Pregnancy Scale* and the way in which the women gave birth to their babies ($p = 0.008$, U = 996.50, z = -2.657), in the sense that those who had a natural birth had a higher score on this scale (Mdn = 40.50), compared to those who underwent a caesarean section (Mdn = 33.50).

The results of the Mann-Whitney test ($p = 0.001$, U = 622.50, z = -3.462) showed that there was a significant difference in the total score on the DAP scale and the item that investigated whether women had medical investigations during pregnancy. Thus, the total DAP scores were significantly lower in women who had these analyses (Mdn = 35.00), compared to women

who did not have medical investigations during pregnancy (Mdn = 43.00). Additionally, the results of the Mann-Whitney test showed that there was a significant difference in terms of the total DAP score for the variable that measures whether the women were advised by a gynecologist during pregnancy (p = 0.001, U = 259.00, z = -3.355). Thus, women who were not followed or advised by any doctor during pregnancy had a significantly higher score on the DAP scale (Mdn = 51.50), compared to those who were advised by a gynecologist, regardless of whether this was a woman (Mdn = 35.00) or a man (Mdn = 35.00).

A Mann-Whitney U test was run to determine if there were differences in the DAP total score between women who felt different degrees of pain during pregnancy. Thus, the results (p = 0.042, U = 5.00, z = -2.030) showed that those who felt a little pain during pregnancy obtained a significantly lower score on the DAP scale (Mdn = 24.00), compared to those who felt the highest degree of pain (Mdn = 42.00).

There were significant differences on the DAP scale among women depending on how concerned they were with their health and the fetus status during pregnancy (p = 0.001, U = 622.50, z = -3.462). Thus, women who had had medical investigations during pregnancy had a significantly lower score on the DAP scale (Mdn = 35.00), compared to those who had not (Mdn = 43.00).

A Kruskal-Wallis H test was conducted to determine if there were differences in total DAP scores between the type of relationship that mothers had with the child's father: the "married" (n = 76), "in cohabitation" (n = 29), and "I am no longer in a relationship with the child's father" (n = 5) groups. The mean ranks of the DAP scores were statistically significantly different between groups, $\chi 2(2) = 21.015$, $p < 0.001$. A post hoc Mann-Whitney U test was run to determine which groups were different from which other groups. This post hoc analysis revealed statistically significant differences in the DAP scores between married women (Mdn = 33.50) and women who were cohabiting with the child's father (Mdn = 43.00) (p = 0.001, U = 626.00, z = -3.414); married women (Mdn = 33.50) and mothers that were no longer in a relationship with the child's father (Mdn = 56.00) (p = 0.001, U = 20.50, z = -3.329).

Similarly, the median DAP score for women who were cohabiting with the child's father (Mdn = 43.00) and women who were no longer in a relationship with the child's father (Mdn = 56.00) (p = 0.016, U = 23.00, z = -2.417) was statistically significantly different. In conclusion, married women had a significantly lower score on the DAP scale, both compared to women who lived in cohabitation and to those who no longer maintained a relationship with the child's father.

The Spearman correlation analysis found significant correlations between the age at which women had their first sexual contact and the age at which they had their first pregnancy (r = 0.658, p < 0.001), in the sense that the older the women were when they had their first sexual contact, the later in life their first pregnancy would appear. Our results showed that there was a negative correlation between the total score of the DAP and the age at which women became pregnant for the first time (r = -0.198, p = 0.038), in the sense that the higher the age at which women became mothers for the first time, the lower the score on the DAP scale.

The level of education influences various aspects of sexual life. Thus, the results indicated a significantly positive correlation between the level of education and the age at which women had their first sexual contact ($r = 0.676$, $p < 0.001$), in the sense that the more educated the women were and the more they studied, the older they were when they started a sexual relationship for the first time. Moreover, the level of education correlates with the age at which women became pregnant for the first time, in the sense that the more educated the women were, the older they became pregnant ($r = 0.753$, $p < 0.001$).

A strong positive correlation was identified between the item that measures the degree of satisfaction women had with life during pregnancy and the Apgar score of the child at birth, in the sense that the more satisfied the women were with the way they lived during pregnancy, the higher the child's Apgar score ($r = 0.202$, $p = 0.008$).

The results indicated that the number of children correlated positively with the relationship women had with their families ($r = 0.150$, $p = 0.048$), in the sense that the more satisfied they were with their family relationships, the more children the women had.

At the same time, the number of children correlated negatively with the pain experienced during childbirth, in the sense that the more children the women had, the less pain they experienced during childbirth ($r = -0.164$, $p = 0.031$). In addition, the level of pain felt during childbirth correlated negatively with the age at which women became pregnant ($r = -0.357$, $p< 0.001$), in the sense that the older the women were when they became pregnant, the less pain they felt during childbirth.

Our results showed that there was a negative correlation between the total score of the DAP and the age at which women became pregnant for the first time ($r = -0.198$, $p = 0.038$), in the sense that the higher the age at which women became mothers for the first time, the lower the score on the DAP scale. Similarly, the mother's satisfaction related to the relationship with the child's father, respectively with the gynecologist were strongly negatively correlated with the DAP score, so the more the mothers were satisfied with both the relationships with the child's father ($r = -0.249$, $p = 0.009$) and the gynecologist ($r = -0.269$, $p = 0.005$), the lower the score on the DAP scale.

A strong negative correlation was identified between the total score of DAP and women's satisfaction with the lives they had before becoming mothers for the first time, meaning the higher the women's satisfaction, the lower the DAP score ($r = -0.294$, $p = 0.002$). Similarly, patients' satisfaction with the medical care given to them by the gynecologist in the hospital and satisfaction with the emotional support given by the gynecologist in the hospital were negatively correlated with the total DAP score, in the sense that the more the women were satisfied with the medical care ($r = -0.218$, $p = 0.022$) and emotional support ($r = -0.243$, $p = 0.010$) provided by the gynecologist, the lower the score on the DAP scale.

DISCUSSION

The present study identified the variables that related to the desire of women to avoid a new pregnancy in research conducted in a single center in north-eastern Romania. The results identified that the age, the level of education, the level of

pain, the intention of pregnancy, the type of delivery, and the support offered by the family, partner, or medical staff were very important when it came to wanting a new pregnancy. We found that married women registered a significantly lower score on the DAP scale, both compared to women who lived in cohabitation and compared to those who no longer maintained a relationship with the child's father.

The medical care offered during pregnancy and during hospitalization seemed to influence the DAP scores. Women who had medical investigations during pregnancy had a significantly lower score on the DAP scale compared to those who did not. The more the women were satisfied with the medical care ($r = -0.218$, $p = 0.022$) and emotional support ($r = -0.243$, $p = 0.010$) provided by the gynecologist, the lower the score on the DAP scale.

As the literature proved, the DAP scale was considered to be a very useful tool to identify the desire of women to avoid a new pregnancy. It was shown to be highly predictive of pregnancy, with women with the lowest DAP score having an 80% chance of becoming pregnant within 12 months (16).

One of the most important factors was related to peripartum experiences and self-rated pain during childbirth. Studies showed that women's desire to remain pregnant depends on their previous experience with unwanted pregnancies, the birth of children with comorbidities, and the existence of severe pain and trauma during the previous birth (17, 18).

Our study identified that the more educated the women were, the later they became pregnant again. Some other results from the scientific literature showed that young women in serious relationships, who were depressed, and who were not pursuing postsecondary education had a greater desire for pregnancy (19).

The results proved that the more satisfied the women were with their lives during pregnancy, the lower the score on the DAP scale. The present results are in congruence with some others presented by studies focusing on the desire of female patients to have a new pregnancy; for example, having access to medical care or having support from the partner increases the desire for a new pregnancy. Difficult marital relationships, intimate violence, or low income increase the rate of avoiding pregnancy. Moreover, studies have shown that women with an unintended pregnancy have more children than those with a planned pregnancy (20-23).

The present study has some limitations. First, there is not a large enough number of participants to make the results generalizable. Second, the questionnaire was filled out by women with a minimum level of literacy, and no uneducated women were able to read and fill it out. Third, the study did not take into consideration mental or psychological problems, the religious context, or the ethnicity of respondents that could also influence the decision to become pregnant or avoid pregnancy (24, 25).

CONCLUSIONS

Taking into consideration all the factors that are associated with the desire of women to avoid a new pregnancy, educational, psychological, and medical interventions should be shaped by these variables. Therefore, psychologists, physicians, nurses, and family planning counselors must consider all the challenges that women, teenage or adult, may face when they attempt to have children.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

WEIGHT LOSS AND NUTRITIONAL STATUS IN YOUNG AND MIDDLE-AGED ADULTS: RATIONAL APPROACH AND HEALTH IMPLICATIONS (Abstract): Obesity is considered a major epidemic of the 21st century in many countries including Romania. Often, obesity is correlated with oxidative stress, metabolic syndrome and cardiovascular problems, which on the long-term increases the risk to diabetes and heart failure. The chances of long-term successful weight loss are enhanced by exercise and the sustained exercise is recommended as a non-invasive approach for the prevention and management of modern civilization diseases. **The aim** of the retrospective study was to monitor the evolution of body weight and some indicators that reflected the weight status of young and middle-aged adults, who exercised in an organized manner in gyms in the city of Iasi (Romania) by following the evolution of anthropometric parameters from the monitoring sheets of subjects who performed physical exercises in two gyms in Iasi. **Material and methods**: Data were extracted on socio-demographic aspects (sex, age, level of education, occupation) and physical status (height, weight, body perimeters) at the beginning of the organized physical exercises regimen and after a certain period of regular exercises. **Results:** Moreover, the respondents followed a caloric restrictive diet, using high protein bars to replace one of their meals. The average weight loss rate was -0.83 ± 0.48 kg/month, higher in men (-1.12 kg/month, maximum 2.9 kg/month) than in women (-0.69 kg/month, maximum 3 kg/month). **Conclusions:** Strict diet and exercise regimen monitorization may have a better impact on weight loss, than allowing a free choice of hypocaloric diet and a standard exercise program. However, all available data shows that reducing overweight has long-term benefits on oxidative burden for obese individuals. **Keywords:** EXERCISE, WEIGHT-LOSS, BMI, WAIST-TO-HIP RATIO, DIET RESTRICTION, OXIDATIVE STRESS.

According to World Health Organization, overweight and obesity are defined as abnormal or excessive fat accumulation that presents a risk to health. Obesity is one of the most serious public health problems of the 21st century. Although the causes of obesity are complex, lack of physical activity is considered to be an important causal factor. For example, in a representative sample of American adults, the relative risk

of obesity among physically active people in their free time (≥ 5 rounds of physical activity per week) was ≈ 50% lower than among those who were physically inactive (1-4). Although such an association does not demonstrate a cause-and-effect relationship, scientific reports convincingly suggest that there is a link between the level of physical activity and obesity. Relatively sedentary people are more likely to be obese compared to those who are physically active. The National Weight Control Registry reported results on 3,000 subjects who lost more than 10% of their body weight and maintained it for at least one year: the average loss of > 30 kg (60 lb.) was maintained for another 5.5 years and 81% reported an increase in physical activity with energy consumption of 2445 kcal/week in women and 3289 kcal/week in men (walking, cycling, aerobics, running, climbing stairs) (5).

Despite the relatively modest weight loss associated with structured physical activity programs, the results of large epidemiological studies support the concept that among more active people, regardless of weight loss, the risk of cardiovascular disease, cancer and all-cause mortality are lowered (6-16). The level of physical activity strongly predicted mortality, regardless of body size. Those studies have suggested that it is as important for clinicians to assess the fitness of an overweight or obese subject as it is to assess smoking or measure plasma lipids or fasting blood glucose (17, 18). Similarly, in the Nurses' Health study (which included 116,564 people), a higher level of physical activity in women was associated with a reduced risk of mortality in all body weight categories and regular exercising reduces age-related cognitive impairment along with optimal redox signaling mechanisms (10, 19).

Weight loss has been associated with structured physical activity programs, so there is a current interest in high-energy exercise, especially among cardiac subjects in the recovery phase, as most of them are overweight or obese. A recent trial showed that subjects randomized to an intensive counseling and exercise program designed to determine an energy expenditure of 300-3500 kcal/week, achieved a double weight loss compared to those who followed a classic cardiac recovery program (8.2 ± 4 versus 3.7 ± 5 kg), a greater reduction in abdominal circumference, reduced insulin resistance, improvement in plasma lipid levels and metabolic syndrome (50% versus 31%) (20).

The main objective of the retrospective study was to monitor the evolution of body weight and some indicators that reflect the weight status of young and middle-aged adults who exercised in an organized manner in gyms in the city of Iasi.

Thus, we looked for valid data from the monitoring sheets of the people who frequented gyms for a significant period of time. We wanted to know the socio-demographic characteristics of those subjects and their nutritional status, both initially and their evolution. We were also interested in the elements that contributed to the evolution of body weight in a sustained exercise program, the level of compliance with that method and the pace at which someone could lose weight.

All those elements are meant to establish the effectiveness of exercise in the management of nutritional status. Subsequently, we set out to compare those results with those that used mainly other weight loss methods, especially dietary ones.

MATERIAL AND METHODS

The retrospective research was done by following the evolution of anthropometric parameters from the monitoring sheets of subjects who performed physical exercises in two gyms in Iasi. Data were extracted on socio-demographic aspects (sex, age, level of education, occupation) and physical status (height, weight, body perimeters) at the beginning of the organized physical exercises regimen and after a certain interval of time (minimum 6 weeks) of regular exercises. Additional data, such as on body fat percentage or daily intake of calories and nutrients from ingested foods, were only partially available.

The inclusion criteria for the selection of the monitoring sheets for the study were: adults from Iași county, of professional working age (between 18 and 60 years old), who performed regular exercises in the chosen gyms for at least one hour, at least 3 times a week.

The analysis tools used were:

- in order to assess weight status, BMI was calculated on the basis of height and body weight for the subjects included in the study, both at the beginning of training in the gym and at the end;
- based on weight (w, kg), height (h, cm) and age (a, years) it was possible to estimate the rest energy consumption (Basic Energy Expenditure, BEE) according to the Harris-Benedict equations:

$$BEE\ (women) = 655 + (9.5 \times w) + (1.8 \times h) - (4.7 \times a)$$

$$BEE\ (men) = 66 + (13.7 \times w) + (5 \times h) - (6.8 \times a)$$

- the diagnostic criterion for abdominal obesity was waist perimeter over 94/102 cm for men and 80/88 cm for women;
- the waist-to-hip ratio was calculated;
- the evolution of each parameter was monitored over time;
- links have been established between various parameters.

Applied statistical methods

For statistical analysis, the data were loaded and processed using the functions from *EXCEL, EPIINFO* and *SPSS*. The data obtained were systematized and statistically processed, applying tests of significance corresponding to the type of study. Descriptive statistics used the mean for the parametric characteristics and the median for the non-parametric or ordinal variables.

We used the χ^2 test to compare two or more frequency distributions from the same population, when the expected events were excluded. In the case of low frequencies, we applied the Yates correction of the formula, in order to obtain a higher estimate of the difference. In calculating the significant difference between two averages we used the t-Student test taking into account the measurement of variability and the weight of observations. The correlations were established based on the Pearson (r) and Spearman correlation coefficients, with values between -1 and 1. The closer the value of r is to 1 (direct correlation) or -1 (indirect correlation) parameters are dependent from each other.

The Spearman correlation and the χ^2 test were initially used to discover possible associations between variables. At the end we used the logistic regression (binary, univariate or multivariate) and calculated the odd ratio and the 95% confidence interval (CI) for the significant variables obtained from the initial analysis. A value of $p<0.05$ was considered statistically significant for both analyzes.

The unanimously accepted significance threshold is 95%, i.e., $p=0.05$. The lower

the value of p than that value, the stronger the significance.

RESULTS

Epidemiological characteristics of the studied group

The study group consisted of 143 subjects, 97 women and 46 men in the ratio 2.1:1. The distribution by sex was predominantly female (67.8%).

The structure by age groups was (Fig. 1):

- the mean age of the subjects at study entry was 29.5 ± 7.3 years, ranging from 18 to 50 years;
- the mean age of males was 31 ± 7.9 years with variations from 18 to 50 years;
- the mean age of females was 28.9 ± 6.9 with variations between 18 and 50 years;
- there were no statistically significant differences between the two sexes regarding the average age (T test = 1.556; p = 0.124).

There was an increased distribution of cases that fall in the age group 20-29 years (52.17%), both male and female.

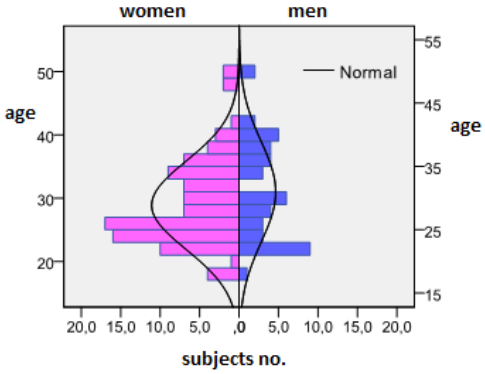

Fig. 1. Distribution by age and sex of the subjects in the study group.

The level of training, as a factor that induces socio-economic conditions as well as the level of education, does not show significant differences between the sexes (X^2 = 1.957; degrees of freedom DF = 2; p = 0.376). The study group recorded 81 cases with higher education (56.6%), 53 cases with higher secondary education (37.1%) and 9 cases with lower secondary education (6.3%) (fig. 2).

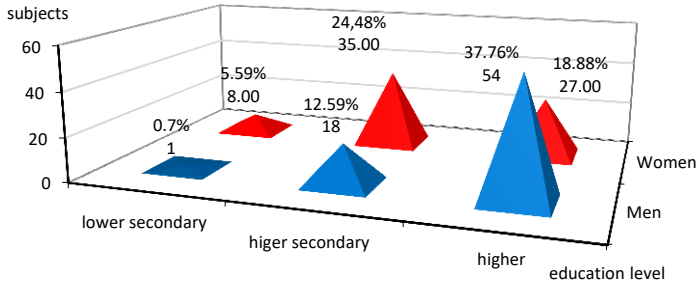

Fig. 2. Distribution by age and sex of the subjects in the study group.

Initial anthropometric characteristics

The subjects from the study group presented the following anthropometric characteristics (tab. I):

- the average waist in males was significantly higher than in females (p<0.001);
- the average weight in men was significantly higher than in females (p<0.001);

- the excess weight over the optimal value was significantly higher in men than in women;
- the average body mass index (BMI) showed statistically significant differences between the sexes in favor of the male sex ($p<0.001$);
- significant differences were found between the two sexes in terms of waist perimeter ($p<0.001$), but not in terms of the hip perimeter ($p> 0.05$).

A comparative view between the male and female groups is given in second table.

TABLE I.

Initial anthropometric characteristics

Characteristics	Total				Women				Men			
	Min	Max	Mean	SD	Min	Max	Mean	SD	Min	Max	Mean	SD
Age (years)	18	50	29.6	7.3	18	50	28.9	7.0	18	50	31.0	7.9

Surplus weight (kg)	14.0	11.6	29.30	11.8	-7.302	0.000	-15.4	-19.6	-11.2
Surplus weight (%)	24.6	19.3	41.10	15.6	-5.480	0.000	-16.6	-22.6	-10.6
BMI (kg/m^2)	26.1	4.20	33.00	3.80	-9.773	0.000	-6.90	-8.3	-5.5
Waist (cm)	84.2	14.4	104.9	13.8	-8.257	0.000	-20.7	-25.6	-15.7
Hips (cm)	99.5	11.4	98.60	8.90	0.493	0.623	0.90	-2.6	4.3
Waist-to-hip ratio	0.80	0.1	1.100	0.10	-12.059	0.000	-0.20	-0.3	-0.2

It is worth mentioning that that 41 normal-weight women have also done physical exercises at the gym. Of those, 6 weighed less than the optimum and 35 exceeded

their optimal weight (on average by 5.8 kg, ranging between 0.6 and 11.9 kg). The excess weight compared to the ideal weight for females was on average 15.1 kg, varying between 0.6 and 57.7 kg, and for males of 29.4 kg, with variation between 7.3 and 57.5 kg (fig. 3).

The average BMI was 26.1±4.2 kg/m^2 in women, and 33.0±3.8 kg/m^2 in men, with a significant difference between the sexes (p = 0.001) (tab. II, fig. 4).

The classification into different categories of body weight (according to the BMI criterion) showed that less than a third of the participants had a normal weight. Men who entered the gym with the intention of losing weight were overweight (21.7%) or had varying degrees of obesity (78.3%) (fig. 5). In women, the situation was different (χ^2 = 59.79, DF = 2, p <0.001), 42.2% of them being normal weight and only 14.4% being obese.

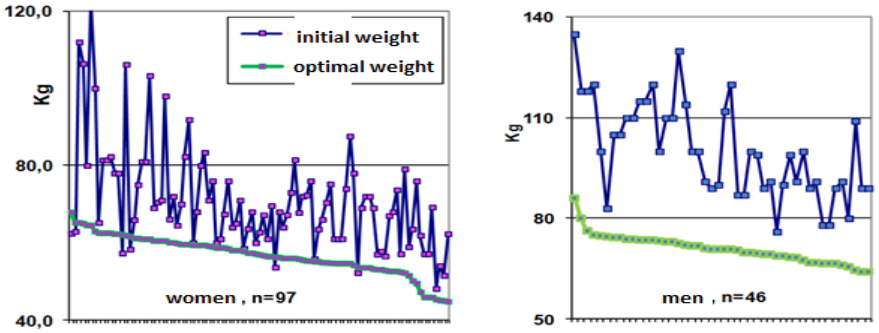

Fig. 3. Differences between the initial weights of the subjects and their ideal weight.

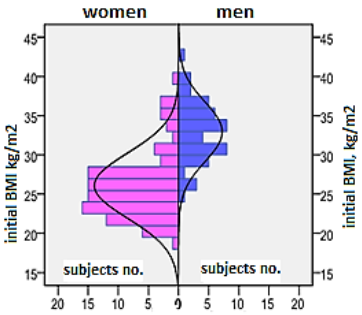

Fig. 4. Distribution of cases according to initial BMI

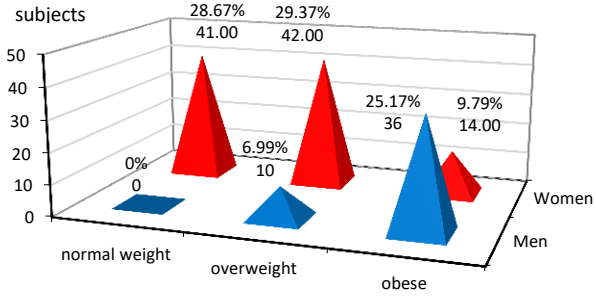

Fig. 5. Initial nutritional status by sex (% of total)

Initial body perimeters

The initial waist perimeter in females varied from 65cm to 126cm, registering an average value of 84.2 ± 14.4 cm, and in males the variation ranged from 85 to 135 cm, with an average of 104.9 ± 13.8 cm, with significant differences between sexes (p <0.001) (fig. 6).

Using the waist perimeter as a diagnostic criterion, abdominal obesity was present in 45.7% of men and 39.2% of women. The abdominal perimeter was normal in only

38.5% of participants, 45.5% of women and 23.9% of men (fig. 7). There were significant differences between the two sexes ($p < 0.05$).

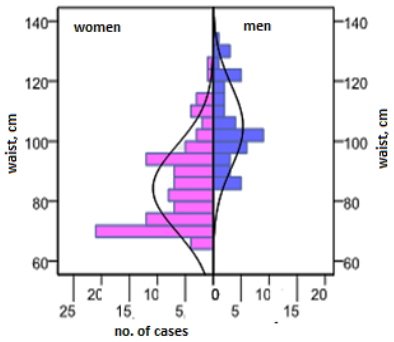

Fig. 6. Distribution of the cases according to the initial waist perimeter (cm).

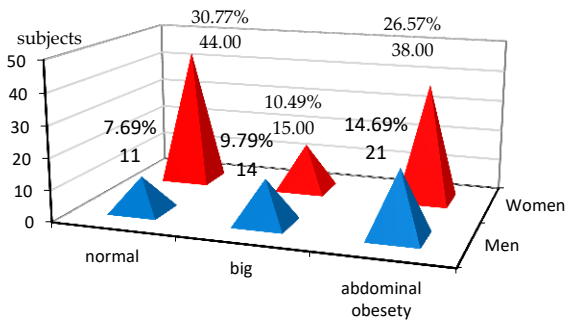

Fig. 7. Abdominal obesity among study participants.

The two diagnostic criteria (abdominal perimeter and BMI) for characterizing the nutritional status were strongly correlated with each other ($p < 0.001$) (fig. 8). The Pearson correlation index had high values in both women ($r = 0.736$) and men ($r = 0.748$).

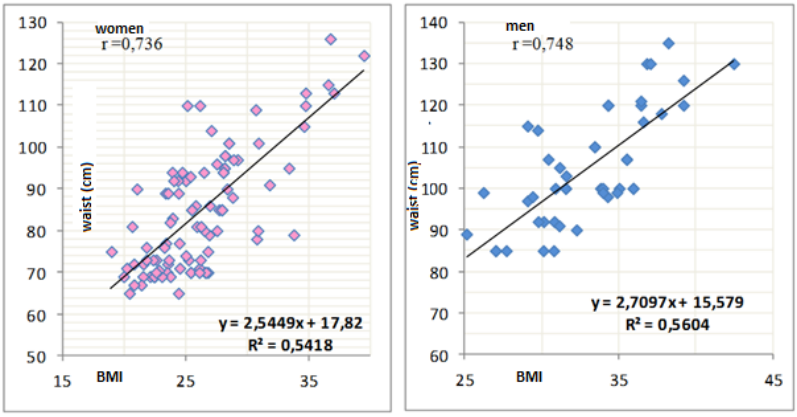

Fig. 8. Correlation between BMI and waist circumference.

The initial hip perimeter registered slightly lower average values in males compared to females, but the difference was not statistically significant ($p > 0.05$). The values of the initial hip perimeter varied in the range of 78-132 cm in females, with an average of 99.5 ± 11.4 cm, while in males the limits were in the range of 83-124 cm, with an average of 98.6 ± 8.9 cm (fig. 9).

The calculated waist-to-hip ratio was 0.85 in women and 1.1 in men ($p < 0.001$).

Basal metabolism. The calculated resting energy consumption was significantly lower in women (1495 kcal/day) than in men.

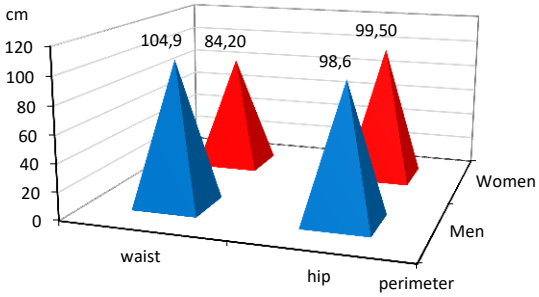

Fig. 9. Average values of body perimeters (cm).

The evolution of the studied parameters during the exercise program

There was a recorded period of 8.98 ± 4.7 months during which the evolution of body weight through physical exercises at the gym was evaluated. It is worth mentioning that the duration of participation in physical exercises in the gym was shorter for women (7.37 ± 4.4 months) than in men (12.38 ± 3.4 months) (p <0.001).

For the whole group, the subjects lost on average -8.1 ± 6.82 kg (-9.2% of body weight) and -7.6 ± 5.3 cm from the abdominal perimeter (tab. III). During the weight-loss period, the evolution of all anthropometric indicators that characterize the nutritional status was statistically significant, with a very high degree of significance (p <0.001), both in men and women (tab. III).

TABLE III.

Evolution of anthropometric parameters

There were also differences between the two sexes - men lost 13.4 kg (reducing their excess weight by 18.6%) and women 5.5 kg (with a difference of -9.5% in terms of excess weight). The reduction of BMI, it was higher in men (-4.35 kg/m^2) than in women (-2 kg/m^2). The waist perimeter, there was a double reduction in men (-11.3 cm) compared to women (-5.8 cm).

Initially, most women were normal or overweight (86.6% of them), while men were in the opposite situation, as the majority (78.3%) were obese (tab IV). Men had significantly higher degrees of obesity, one subject being morbidly obese and 14 were severely obese, compared to only 4 women that were in the category of grade I obesity. The differences in levels of BMI between the two sexes remained significant even at the end of the study, however, the differences in the category of abdominal perimeter disappeared.

TABLE IV.
Characterization of the study group according to the initial and final anthropometric parameters

Parameter	Category	Total n=143		Women n=97; 67.8 %		Men n=46; 32.2 %		χ^2 Test
		n	%	n	%	n	%	
Initial BMI	normal weight	41	28.7	41	28.7	0	0	$\chi^2 = 59.788$ DF = 2 p<0.001

Although the weight loss was significant, the optimal weight was only achieved in a few cases. In the case of some women, a final weight lower than the one considered optimal was reached (fig. 10).

The data obtained (fig. 11) showed that 29.4% of the subjects (17.5% women and 11.9% men) lost between 5 and 10 kg, and 17.5% lost between 10 and 15 kg. Weight loss of over 20 kg (maximum 36.3 kg) was also recorded in 7.7% of subjects (10 men and one woman).

By comparing the weight lost to the initial weight of the subjects, we notice that about a quarter of them lost between 5-10% of their initial weight and a third of women

lost less than 5% of their body weight. In total, 41.3% of subjects lost over 10% of their initial body weight, and 5.6% lost more than 20% (fig. 12).

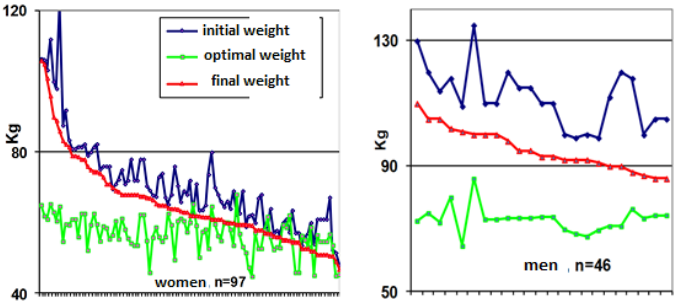

Fig. 10. Evolution of body weight compared to the initial weight of the subjects and to the ideal weight.

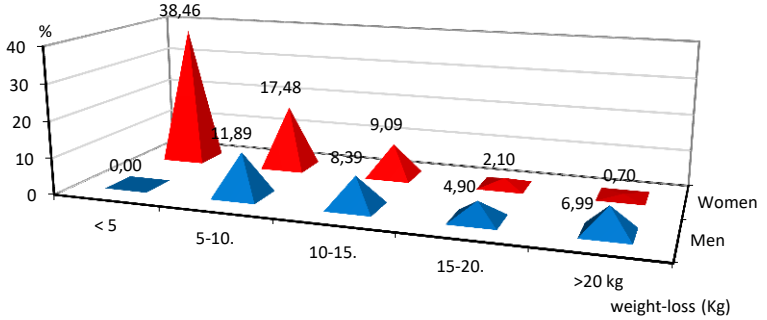

Fig. 11. Distribution of subjects according to weight lost (χ^2 = 54.24; DF = 4; p<0.001).

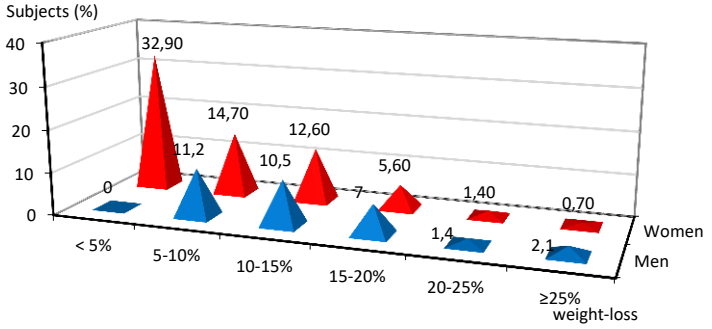

Fig. 12. Distribution of subjects according to the percentage of body weight lost during the weight loss program (χ^2 = 35.50; DF = 5; p = <0.001).

Other indicators of weight loss, used mainly in reporting the results of surgical treatment of obesity (bariatric surgery) (18-22), are the percentage of decreased BMI and the percentage of decreased weight. In our study, the BMI decrease was -9.54% for the whole group, with lower values for women (-7.66%) than for men (-13.33%). That index adjusts the percentage of weight loss, taking into account the person's height,

being more useful in interpreting the degree of excess weight. The percentage of weight loss primarily targets the effect of therapy. In our study, 42.4% was the percentage for the whole group, with higher values in men (45.7%) than in women (39%).

Statistically significant changes ($p < 0.001$) were also registered in the case of body perimeters. The waist perimeter decreased on average by -5.9 ± 3.9 cm for women, and by 11.3 ± 6.1 for men. As a result, the final abdominal perimeter had an average in the optimal range. The waist-to-hip ratio decreased in men from 1.06 to 1.02 and in women from 0.85 to 0.83.

Involvement of various factors on the percentage of weight loss

By using the Spearman coefficient and regression techniques/ANOVA we identified significant correlations between the weight loss percentage (relative to the initial weight) and the factors that influenced the process: program duration ($r = +0.765$, $p < 0.001$) (fig. 13), initial BMI ($r = +0.44$, $p < 0.001$) (fig. 14), initial excess weight (kg), which also influenced the theoretical goal set initially ($r = +0.452$, $p < 0.001$). From the analysis of the obtained data, it was found that the percentage weight loss achieved was not statistically significantly correlated with age ($r = -0.055$, $p = 0.514$).

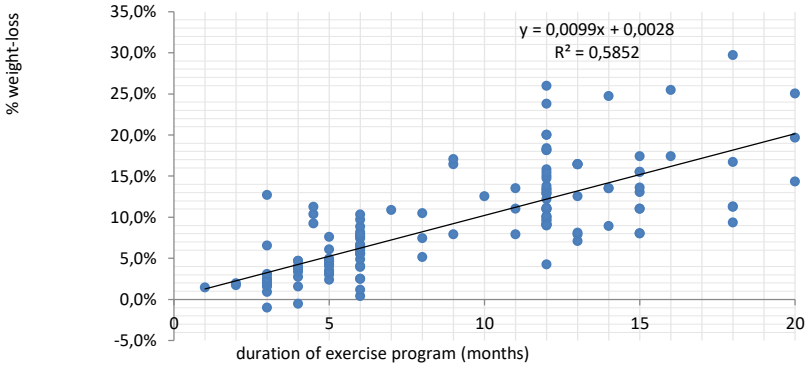

Fig. 13. The influence of the duration of the program on the weight loss percentage.

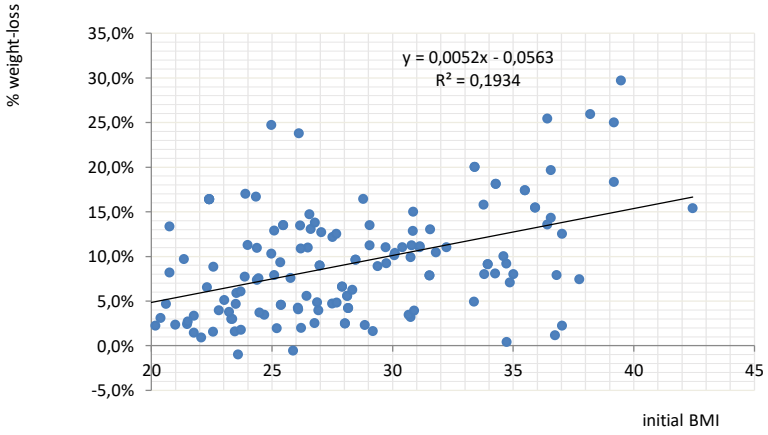

Fig. 14. Influence of initial BMI on weight loss.

The average weight loss rate was -0.83 ± 0.48 kg/month, higher in men (-1.12 kg/month, maximum 2.9 kg/month) than in women (-0.69 kg/month, maximum 3 kg/month), with statistically significant differences between the sexes (t-test = 4.955, $p < 0.001$). We also found that the average monthly rate of weight loss was negatively correlated with age ($r = -0.315$, $p < 0.001$).

DISCUSSION

One of the limiting factors of our study was that the information from the monitoring sheets could only partially characterize the diet of the participants. What we know is that the subjects resorted to caloric restrictions in food intake. Comparing our data to that from the scientific literature, we found that in our study, weight loss was higher than that reported in studies based on exercise without changing the diet but falls between the values obtained in studies that combined diet with exercise or resorted to medication.

From the observation sheets we deduced that the participants also resorted to caloric restrictions in food intake, but we could not characterize the used diet. Using hypocaloric diets remains a desirable approach to enhance the efficacy of the exercise program. Moreover, excess food intake leads to oxygen reactive species supra production at the mitochondrion level, which in turn induces inflammation and prooxidative enzyme activation (e.q. malondialdehyde, NADPH oxidase etc.). Excess nutrients (especially sugar derived products and fat-rich foods) in patients with diabetes and endothelial disfunction or hypertension enhances multiple factors that aggravate metabolic syndrome and cellular processes. Available patients' data indicates that lipid peroxidation and oxidative stress is positively correlated to increased waist circumference and BMI, while adiponectin is negatively correlated to these parameters (26, 27). This also indicates that there is a direct relation between oxidative stress and weight gain, suggesting that losing weight or weight management is a good preventive approach to decrease the high levels of oxygen reactive species in obese and overweight people (28).

The group was homogeneous in terms of epidemiological characteristics. From the point of view of anthropometric and nutritional parameters, some statistically significant differences were found between women and men. The average BMI in men was higher than in women (33.0 ± 3.8 kg/m^2 *vs.* 26.1 ± 4.2 kg/m^2), and the classification in different categories of body weight using the BMI criterion showed significant differences between the sexes. All men who entered the gym with the intention of losing weight were overweight or had varying degrees of obesity, while more than 40% of women were normal weight, and some of them (6.2%) had an initial weight below the optimum.

Those significant differences between the sexes could be explained by different motivation - men resort to weight loss methods when weight is exceeded and health is endangered, but women can also be motivated by aesthetics. Interestingly, motivation is behind the efficacy of most dietary and exercise programs (29-31). Moreover, the physical activity in itself has a positive effect on the mindset of patients (enhancing self-esteem) and on their lifestyle (32). More recent data indicates that type 2 diabetes can be bounced back with the help of a 3-step structured program that includes diet management, restrictions and food reintro-

duction, along with long-term weight loss maintenance and monitorization. Even if the results were promising, some concerns and controversies were noted among the participants and supervising specialists, especially related to taking patients off the anti-hypertensive and anti-diabetic medication (33). Although the voluntary participants in our study did not declare any health problems, the obesogenic lifestyle increases the risk for cardiovascular complication and type 2 diabetes. Habit changes depend mostly on self-motivation when no psychological support is available. This explains the need to include specialized support and advice in regard to proper diet and physical activity approach for long-term weight management.

There was 8.98 ± 4.7 months recorded period for evaluating the evolution of body weight through physical exercises at the gym and for the entire group there was an average loss of 8.01 ± 6.82 kg, i.e., -9.2% of body weight and -7.6 ± 5.3 cm from the waist perimeter. The duration of exercise period in the gym was shorter for women (7.37 ± 4.4 months) than for men (12.38 ± 3.4 months), probably due to the fact that the initial excess weight was higher in men than in women.

The average weight loss rate was -0.83 ± 0.48 kg/month, higher in men (-1.12 kg/month, maximum 2.9 kg/month) than in women (-0.69 kg/month, maximum 3 kg/month) and was negatively correlated with the age of the subjects.

In a 2007 meta-analysis (34), the average weight loss was 5-8.5 kg (5-9%) in the first 6 months of weight-loss regimen involving calorie-restricted diets or weight loss medication. In contrast, groups that only exercised or received advice showed minimal weight loss, regardless of the evaluation period. In interventions that combined diets with caloric restrictions in combination with exercise, there were moderate weight loss after 6 months, and in studies with a much longer duration of 48 months, an average weight loss of 3-6 kg (3-6%) was maintained for a long time.

Although the weight loss following the physical effort in the gym was significant, the final average weight obtained exceeded the calculated optimal weight by 10.9 ± 10.64 kg, i.e., by an average of 17.4 ± 16.7%. However, at the end of our research 16 people had less than the calculated optimal weight and another 8 reached the ideal weight ± 1 kg.

The surplus compared to the ideal weight for females was on average 15.1 kg, and for males 29.4 kg. Abdominal obesity was initially encountered in 41.3% of study participants (39.2% of women and 45.7% of men). The calculated waist-to-hip ratio was 0.85 in women and 1.1 in men. Those aspects confirmed that there is a higher tendency to store adipose tissue in men in the "apple" distribution, which implies an increased metabolic risk.

Some online weight loss program and activity tracker reveal significantly more weight loss at 3 months and a higher weekly moderate-to-vigorous intensity physical activity is associated with greater long-term weight loss and weight maintenance (35, 36).

Another review of the scientific literature on the role of physical activity in bodyweight management (36) pointed out that although weight loss through exercise alone was significantly greater than zero, the absolute and percentage values were modest, but if a diet change is added to the physical exercises, the differences in weight loss become significant. Weight loss depends on the energy difference be-

tween intake and consumption. That difference can be increased by combining low-calorie diets (low intake) with structured exercise programs (high consumption).

However, it was found that there may be other benefits of practicing physical activities for weight loss, such as better weight loss, with mostly fat loss and better long-term maintenance of weight (higher metabolic rate) (37). Exercise practiced three times a week, in combination with replacing one meal a day with a nutritional formula can increase fitness and improve the body's composition, but the intake of thermogenic substances does not bring additional benefits (38). More research is ongoing in terms of evaluation of direct correlations between the oxidative status and weight-loss program. Taking into account all available data, the evaluation of physical activity pattern cand be a good predictor for the health status, early cardiovascular risk and metabolic syndrome outcome.

CONCLUSIONS

Our research indicates once again that physical activity, especially high energy exercises, and small changes in diet without strict restrictions contribute to weight loss. Moreover, the voluntary subjects included in the study did not abandon the exercise program during the observation period. However, a long-term body weight management program should include psychological and motivational support for overweight and obese individuals, thus ensuring better health consequences by maintaining systematic physical activity.

INSTITUTIONAL REVIEW BOARD STATEMENT

Ethical review and approval were waived for this study due to the obtaining of individual consent of all voluntary participants, for which no identification data was used. No clinical testing was required, only retrospective data from the completed data sheets was used.

INFORMED CONSENT STATEMENT

Informed consent was obtained from all subjects involved in the study.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest. B. Huzum, I. Chirila and Riana Maria Huzum had equal contribution and should be regarded as main authors of the manuscript.

RETROSPECTIVE STUDY ON THE PREVALENCE OF ORAL SYMPTOMS IN THE SPECIFIC MANIFESTATIONS OF PATHOLOGY CAUSED BY SARS-CoV-2 VIRUS (Abstract): The aim of this study is to retrospectively analyze the prevalence of oral pathology in the range of symptoms characteristic of the clinical picture caused by the SARS-CoV-2 virus. The study was carried out on 779 patients with COVID-19, hospitalized between September 2020 and April 2021 in CF Hospital from Iasi, Romania. The sample's structure on genders was almost perfectly equilibrated (49.6% men and 50.4% women), with age spread within all age ranges, between 7 and 93 years; around a half of patients were adults between 40-59 years old (45.6% men and 49.4% women). The percentage of asymptomatic patients is significantly higher among those afebrile (27.7%) compared to febrile ones (6.1%). Among the afebrile, 65.2% have 1-4 symptoms, compared to 87.7% of the febrile, and 7.1% have 5-9 symptoms, compared to 6.1% of the febrile. We noticed increased incidences of oral symptoms in patients with aggravated condition (febrile) by comparison with the others, in most cases - with only one exception, gum bleeding, which is slightly more frequent in case of afebrile / sub febrile patients (59.2% cases compared with 55.1% cases of febrile patients). Oral signs including dysgeusia, xerostomia, oral mucosal lesions and periodontal pathology could be associated with SARS-CoV-2 infection or equally could be considered secondary lesions of COVID19 infection, which are extremely useful elements in the early diagnosis of people with COVID19. **Keywords:** COVID-19, SARS-CoV-2, ORAL SYMPTOMS, XEROSTOMIA, DYSGEUSIA, GENERAL STATUS.

The coronavirus pandemic triggered in 2019 affected an impressive number of people, namely 110, million and spread to 224 countries (1-5). The pathology of COVID 19, characterized by a symptomatic polyvalence, has the SARS-CoV-2 virus as a pathogen. The clinical aspects of a patient diagnosed with the SARS-CoV-2 virus is particularly complex, bringing together multiple signs and symptoms, found in the different territories without excluding the oral territory, a particularly important level in the early diagnosis of these pathologies (6-9).The frequent symptomatology for this

type of pathology was represented by fever, cough, dyspnea but also by a series of oral signs that were found in a quantifiable proportion (10-13).The most common oral manifestations in patients with COVID 19 were dysgeusia and xerostomia. Dysgeusia refers to the inability of patients to identify the taste of food or drink, a symptom with profound implications for the quality of life of affected patients (13-16). It is important to note that oral signs associated with coronavirus persisted in patients for three months after the general condition symptoms had subsided to disappearance, which underlines the fact that oral symptoms could materialize into side effects of COVID 19 pathology (17-20). Oral symptoms associated with COVID 19 infection were dysgeusia, xerostomia, oral mucosal lesions, macroglossia, temporomandibular joint disorders and a range of periodontal disease (21-25).

The aim of this study is to retrospectively analyze the prevalence of oral pathology in the range of symptoms characteristic of the clinical picture caused by the SARS-CoV-2 virus.

MATERIALS AND METHODS

The study was carried out on 779 patients with COVID-19, hospitalized between September 2020 and April 2021 in CF Hospital from Iasi, Romania. The sample's structure on genders was almost perfectly equilibrated (49.6% men and 50.4% women), with age spread within all age ranges, between 7 and 93 years; most patients (around a half of them were adults between 40-59 years old (45.6% men and 49.4% women). The detailed demographic features of the studied sample are specified in first table.

TABLE I.

The sample's structure on genders and age groups

		Gender				Total	
		m		F			
		N	%	N	%	N	%
Age range	under 20 years	8	2.1%	7	1.8%	15	1.9%
	20-29 years old	24	6.2%	26	6.6%	50	6.4%
	30-39 years old	50	13.0%	44	11.2%	94	12.1%
	40-49 years old	89	23.1%	90	22.9%	179	23.0%
	50-59 years	87	22.5%	104	26.5%	191	24.5%
	60-69 years	73	18.9%	63	16.0%	136	17.5%
	70-79 years	36	9.3%	36	9.2%	72	9.2%
	over 80 years	19	4.9%	2.3	5.9%	42	5.4%
Total		386	100.0%	393	100.0%	779	100.0%

The statistical analysis was performed in *SPSS 29.0*. The qualitative data were reported as absolute frequencies and percentages, and the quantitative data were reported as averages and standard deviations. The associations between qualitative data were investigated using the Chi-squared test. Binary logistic regression (Forward LR) was used to investigate the cumulative effect of risk factors for aggra-

vated evolution. The ROC analysis was performed in order to identify the cut-off values of quantitative parameters for aggravated evolution (febrile state). The values of $p < 0.05$ were evaluated as statistically significant, and the values of $p < 0.01$ were evaluated as statistically highly significant.

RESULTS

We focused our study on the investigation of patients' evolution, characterized through its severity - febrile patients *vs.* afebrile or sub febrile patients. Most patients had a good evolution, being afebrile 665 - 85.4%), while 65 patients (8.3%) were sub febrile for 1-2 days and 49 patients (6.3%) were febrile 1-3 days. Afebrile and sub febrile patients were included in the same category, febrile patients being investigated separately.

No statistically significant differences are found between febrile and afebrile patients neither in terms of their distribution by gender nor by age ranges - therefore, these two parameters do not function as risk factors for the unfavorable evolution of patients (tab. II).

TABLE II.

Distribution by gender and age range according to evolution

		Evolution							
		Afebrile / Sub febrile		Febrile		p	OR	95% CI	
		n	%	n	%			Lower l.	Upper l.
Gender	male	360	49.3%	26	53.1%	0.612	-	-	-
	female	370	50.7%	2. 3	46.9%				
Age	under 60 years	495	67.8%	34	69.4%	0.819	-	-	-
	over 60 years	235	32.2%	15	30.6%				

Among the investigated symptoms, significantly increased percentages are observed in febrile patients compared to others in the case of cough (59.2% *vs.* 38.9%), fever at onset (40.8% *vs.* 16.3%), loss of appetite (16.3% *vs.* 6.0%), nausea (10.2% *vs.* 2.7%) and diarrhea (10.2% *vs.* 1.9%). The highest risk is recorded for patients with digestive disorders: diarrhea (OR = 5.812) and nausea / vomiting (OR = 4.034) (tab. III).

TABLE III.

Distribution of recorded symptoms according to evolution

Other	45	6.2%	4	8.2%	0.540	-	-	-
Asymptomatic	202	27.7%	3	6.1%	0.000**	0.170	0.052	0.554

We also investigated by comparison in these two categories of patients the presence of oral symptoms (tab. IV). We noticed increased incidences of oral symptoms in patients with aggravated condition (febrile) by comparison with the others, in most cases - with only one exception, gum bleeding, which is slightly more frequent in case of afebrile/sub febrile patients (59.2% cases compared with 55.1% cases of febrile patients). The most common oral symptoms met in the case of febrile patients were taste altered (81.6% cases) and Candida (79.6% cases). Despite these specific elements, we didn't report, anyway, statistically significant differences between the two samples investigated.

The percentage of asymptomatic patients is significantly higher among those afebrile (27.7%) compared to febrile ones (6.1%). Among the afebrile, 65.2% have 1-4 symptoms, compared to 87.7% of the febrile, and 7.1% have 5-9 symptoms, compared to 6.1% of the febrile (tab. V).

TABLE IV.

Distribution of recorded oral symptoms according to evolution

	Evolution				
	Afebrile / Sub febrile		Febrile		p
	n	%	n	%	
Xerostomia	324	44.4	28	57.1	0.922

Candida	520	71.2	39	79.6	0.208

TABLE V.

Distribution of symptoms according to their number, according to evolution

		Evolution, p = .000**			
		Afebrile / Sub febrile		Febrile	
		n	%	n	%
No. symptoms	0	202	27.7%	3	6.1%
	1	82	11.2%	5	10.2%
	2	132	18.1%	3	6.1%
	3	178	24.4%	24	49.0%
	4	84	11.5%	11	22.4%
	5	36	4.9%	2	4.1%
	6	10	1.4%	1	2.0%
	7	5	0.7%	0	0.0%
	9	1	0.1%	0	0.0%
Total		730	100.0%	49	100.0%

The AUC coefficient for the number of symptoms is 0.665, with a confidence interval between 0.599 and 0.731, statistically significant (p = .000**), but with little potential for predicting the evolution of patients. The identified cut - off value is 2.50, with a fairly good sensitivity of 0.776 and a specificity of 0.570 (fig. 1) - so the risk of worsening evolution due to fever increases in patients with at least 3 cumulative symptoms, compared with the others.

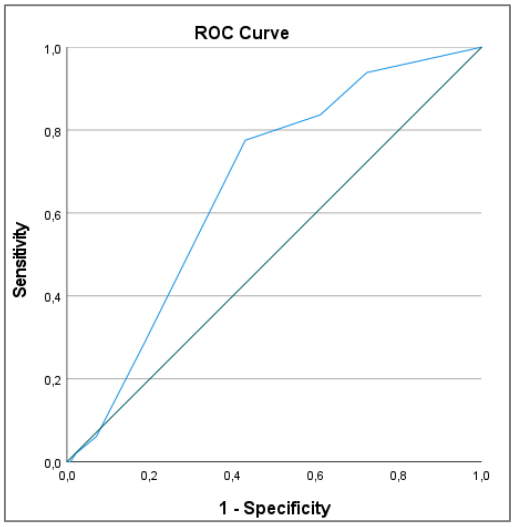

Fig.1. No. symptoms *vs.* evolution - ROC curve

The overall share of patients with comorbidities is slightly higher among those with fever (69.4%) compared to those with afebrile illness (63.8%), but the difference recorded is not statistically significant; the separate analysis on particular comorbidities highlights the same phenomenon; thus, among febrile patients there are

slightly more cases of cardiovascular diseases (63.2% *vs.* 61.4%), liver diseases (10.2% *vs.* 8.2%), kidney diseases (10.2% *vs.* 8.4%), anemia (6.1% *vs.* 2.3%), thyroid disorders (6.1% *vs.* 4.1%) and neoplasm (6.1% *vs.* 3.8%) , but without the threshold of statistical significance being reached (tab. VI).

TABLE VI.
Distribution of registered comorbidities according to evolution

Neoplasm	28	3.8%	3	6.1%	0.437	-	-	-
Other	88	12.1%	4	8.2%	0.414	-	-	-

The number of cumulative comorbidities does not differ statistically significantly in febrile patients compared to the others, although the share of patients without comorbidities is slightly higher among those afebrile (36.2%) compared to febrile ones (30.6%); among febrile patients, both the share of cases with 1-3 cumulative comorbidities (57.2% *vs.* 54.5%), and the share of cases with 4-7 cumulative comorbidities (12.2% *vs.* of 9.2%) (tab. VII).

Multivariate analysis by binary logistic regression identifies 3 significant predictors for the evolution aggravated by febrile state, namely: the presence of fever at the onset ($p = 0.015^{**}$), of diarrhea ($p = 0.026$) and of at least 3 cumulative symptoms ($p = 0.002$) - (tab. VIII).

TABLE VII.
Distribution of comorbidities according to their number, according to evolution

		Evolution, p = .175

No. symptom	0.002	3.237	1.549	6.766

We also investigated the influence of pulmonary changes on the evolution of patients; we found that the changes statistically significantly associated with worsening evolution are ground glass appearance (observed in 76.6% of febrile patients and 58.7% of others) and confluence (observed in 14.9% of febrile patients compared to 6.1 % of others). Other pulmonary features found in higher percentages in febrile patients were condensation (12.8% *vs.* 6.7%), consolidation (4.3% *vs.* 3.2%), and fibronodular sequelae (8.5% *vs.* 7.0%). 19.3% of afebrile patients have normal pulmonary appearance, compared to only 8.5% of febrile ones (tab. IX).

Another element recorded at the admission of the patients was the CRP level. Almost all patients had elevated CRP, the mean value recorded being 28.8944 ± 46.11459 mg/l, with a range of variation between 0.04 mg/l and 293.31 mg/l. It was also found that CRP values are significantly higher in men compared to women, and also in patients over 60 years old, with symptoms and comorbidities (tab. X).

TABLE X.

Batch CRP values (mg/L) - descriptive statistics parameters

		N	Mean	SD	Minimum	Maximum	p
Total		730	28.8944	46.11459	0.04	293.31	
Sex	male	365	34.9502	52.60998	0.04	288.00	0.000**
	female	365	22.8386	37.65097	0.11	293.31	
Age range	under 60 years	493	19.7890	37.87123	0.11	293.31	0.000**

	yes	480	36.2231	51.86774	0.04	293.31	

There is a clear association between increased CRP values and the presence of lung changes on CT; thus, patients with altered CT have an average CRP value of 32.6039 ± 46.37504 mg/l, with a maximum reaching 293.31 mg/l, compared to patients with normal CT, with a significantly lower average CRP value at 9.1630 ± 23.70186 mg/l. Significantly increased values for CRP are observed in patients with ground glass appearance and confluence; in the case of other pulmonary changes (condensation, consolidation, opacity, crazy appearance paving , pulmonary nodule), although the CRP values are also higher, the differences do not reach the threshold of statistical significance (tab. XI).

ROC analysis for CRP values at admission reveals an AUC coefficient (Area under Curve) of 0.756, with a confidence interval between 0.711 ÷ 0.802, statistically significant (p = 0.000**) and with moderate efficiency in predicting pulmonary changes - table 11. The identified cut - off value is 7.800, corresponding to a sensitivity of 0.620, quite low, and a specificity of 0.810 - therefore, a CRP value below the limit of 7.800 represents an 81%.

The efficiency of CRP values in predicting the appearance of ground glass is lower (0.633), for the cut - off value of 10.52, with rather poor sensitivity and specificity. Similarly, the effectiveness of CRP values in predicting the appearance of confluence is also relatively low (0.690), but the identified cut - off value of 6.245 has a fairly good sensitivity of 0.889, which means that patients with CRP above the limit of 6.245 will have confluence in 88.9% of cases (tab. XII, figs. 2, 3, 4). The CRP values bigger than 6.245 but smaller than 7.800, which correspond to a risk of confluence of 88.9%, and to a probability of 81% to not have major changes on CT - were identified in a subsample of 43 patients, having the following features: 12 patients (27.9%) have confluence, but only one of them has also changes on CT, being febrile; other 3 patients have changes on CT but are not febrile, and the rest of 8 patients are also afebrile and the pulmonary CT was not achieved.

TABLE XII.

ROC analysis for CRP values - admission

	AUC	p	95% confidence interval of AUC		Cut -off value	Sensitivity	Specificity
			L. inf.	L. sup.			
Modified CT	0.756	0.000**	0.711	0.802	7.800	0.620	0.810
Ground glass appearance	0.633	0.000**	0.593	0.674	10.520	0.556	0.688
Confluent	0.690	0.000**	0.620	0.761	6.245	0.889	0.426
Evolution - febrile state	0.615	0.008**	0.540	0.689	4.540	0.896	0.331

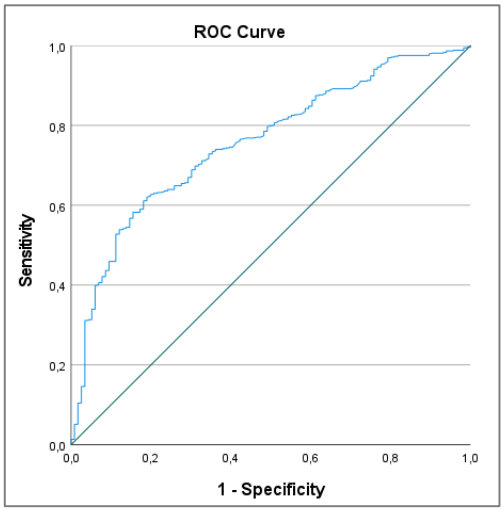

Fig. 2. CRP values *vs.* Modified CT - ROC curve

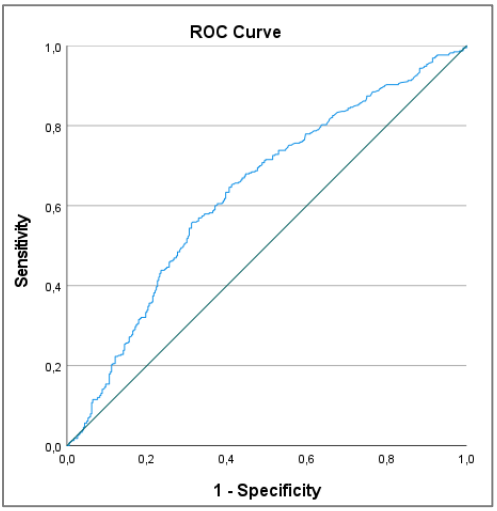

Fig. 3. CRP values *vs.* Ground glass appearance - ROC curve

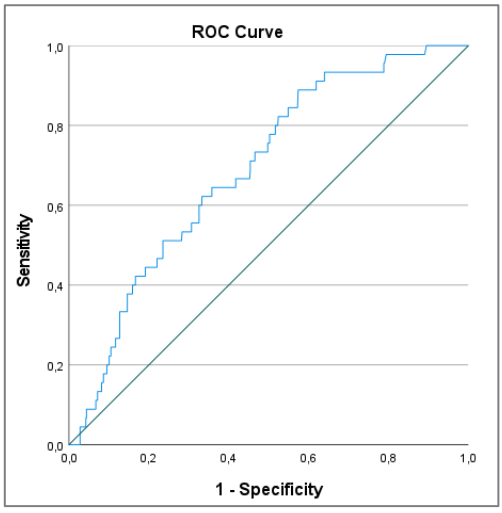

Fig. 4. CRP values *vs.* Confluence – ROC curve

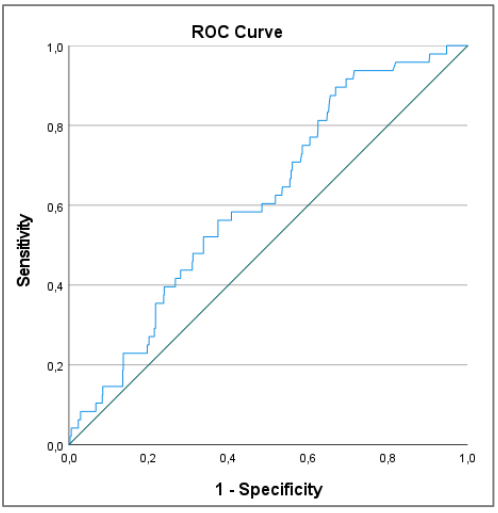

Fig. 5. CRP values *vs.* Evolution – ROC curve

CRP values are almost double in febrile patients (with an average of 41.9288 ± 8.82026) compared to afebrile ones (27.9770 ± 1.71499), the difference being also statistically significant - table 12. The associated AUC coefficient is 0.615, statistically significant but quite reduced, again the cut - off value identified, of 4.540, has a sensitivity of 0.896, which means that patients with CRP above the limit of 4.540 will present a febrile state in 89.6% of cases (tab. XIII, fig. 5).

TABLE XIII.

Comparative CRP values according to the evolution of the patients

		N	Mean	SD	Minimum	Maximum	p
Evolution	Afebrile / Sub febrile	682	27.9770	1.71499	0.04	293.31	0.043*
	Febrile	48	41.9288	8.82026	1.65	285.94	

DISCUSSION

The results of our study are superimposable on those obtained by Amorim dos Santos J, and collaborators (2021), highlighting that xerostomia was a prevalent oral manifestation in these patients diagnosed with SARS-CoV-2 virus (26).

Salivary secretion was frequently affected in patients with COVID 19. There was no significant gender difference but burning sensation and dysphagia was present in these patients. Xerostomia significantly disrupted the comfort of patients with long-term repercussions on dental status. Studies by Gherlone and collaborators in 2021 associated the presence of xerostomia with salivary duct dilatation, which highlights the existence of a significant inflammatory response in the salivary glands (27).

In SARS-CoV- 2 infection oral mucosal lesions were present in a lower proportion than the presence of xerostomia, patients diagnosed with COVID 19 had oral mucosal lesions within 10 days of infection. Geriatric individuals or those who had complications requiring long-term hospitalization with poor hygiene were more susceptible to the presence of oral mucosal lesions.

The results of our study are also consistent with the observations in the study by Amorim dos Santos J and collaborators (2021) regarding the prevalence of fungal infections in patients with SARS-CoV-2 (26). Equally gingivitis and bleeding gums were frequently noted in these patients. Brandão and collaborators in a study conducted in 2021 found the presence of lesions similar to aphthous clinical entities the aspects that individualized them were represented by round or irregular shapes of the presence of an erythematous halo and the entire surface being covered by a white pseudo membrane (28).

Periodontal disease affected a significant proportion of patients who were diagnosed with severe periodontitis. A number of research studies have suggested that periodontal pathogens may aggravate the symptoms of pneumonia or lead to increased levels of systemic inflammatory cytokines.

Almost all patients had elevated CRP at admission, its values being significantly increased in male patients over 60 years of age with symptoms and comorbidities. There is a clear association between increased CRP values and the presence of lung changes on CT, particularly in patients with ground glass appearance and confluence. ROC analysis shows that a CRP value below the cutoff of 7.800 represents an 81% probability that the patient will not have pulmonary complications, and a CRP value above the cutoff of 6.245 is associated with an 88.9% probability that the patient will have confluence. Also, CRP values are almost double in febrile patients compared to afebrile ones, and patients

with CRP above the limit of 4,540 will present a febrile state in 89.6% of cases. The evolution of patients with COVID-19 could be significantly influenced by xerostomia periodontal disease, aspects that required well-managed trajectories of oral health monitoring of these patients.

The limits of the study can be related to the limited therapy of oral pathology in the context of aggravated general condition, the therapeutic solution in the oral area being only for emergencies.

CONCLUSIONS

Most patients had a good evolution, being afebrile or sub febrile, the percentage of febrile patients being 6.3% of the total. Symptoms present in significantly increased percentages in febrile patients compared to others were cough, fever at onset, loss of appetite, nausea/vomiting and diarrhea, without identifying associated comorbidities; multivariate analysis identifies 3 significant predictors for the occurrence of febrile conditions, namely fever at onset, diarrhea and the presence of at least 3 cumulative symptoms.

Pulmonary changes statistically significantly associated with worsening evolution are ground glass appearance and confluence.

Oral signs including dysgeusia, xerostomia, oral mucosal lesions and periodontal pathology could be associated with SARS-CoV-2 infection or equally could be considered secondary lesions of COVID19 infection, which are extremely useful elements in the early diagnosis of people with COVID-19.

INCREASED ANXIETY AMONG HEMODIALYSIS PATIENTS DURING THE COVID-19 PANDEMIC. A SINGLE CENTER EXPERIENCE (Abstract): The COVID-19 pandemic affected millions of people worldwide, and the hemodialysis population was one of the most affected. Anxiety, defined as an affective state characterized by psychomotor restlessness, indistinct fear, and no discernible object, is growing worldwide and among hemodialysis patients, as well. The pandemic has extensively worsened social and economic challenges and has further expanded existing psychosocial alterations in this patient category. With a heightened awareness of their susceptibility to contracting COVID-19 and experiencing severe complications, coupled with concerns about financial instability and the loss of loved ones, the imposition of quarantine and isolation measures has intensified levels of anxiety, depression, and sleep disturbances among these patients. **Materials and methods:** In the current study, all 102 patients included were enrolled in the chronic hemodialysis program at AVITUM-BBRAUN Suceava. All patients included in the analysis completed the Kidney Disease and Quality of Life (KDQOL™-36) questionnaire. **Results:** The findings revealed an increase in anxiety, perception of pain, and sleep disturbances, contributing to an overall low quality of life Score among the participants. **Conclusions:** Chronic kidney disease profoundly impacts the daily lives of HD-patients, affecting not only physical health but also emotional well-being and quality of life. COVID-19 pandemic had an additional negative impact. Providing adequate support and care to patients with chronic kidney disease is crucial for effectively managing the condition and improving their quality of life and adherence to treatment. **Keywords:** QUALITY OF LIFE, COVID-19, ANXIETY, PATIENT SELF-ASSESSMENT, DIALYSIS, OUTCOMES.

Quality of life is determined by individuals' perceptions of their social situation in accordance with their own needs, standards, and aspirations (1). It encompasses physical, mental, and social well-being, as well as the ability to perform everyday tasks (2).

The concept of quality of life includes various elements related to the physical, economic, social, health, and disease situations of individuals. It encompasses the content and nature of activities in which individuals engage, the characteristics of social relationships and processes in which they participate, as well as subjective states of satisfaction, dissatisfaction, happiness, and frustration. The concept of quality of life in relation to health sets out various

dimensions or areas that contribute to overall well-being and satisfaction with one's health status. These include symptoms perceived and reported by the patient, physical function, professional and household activities, social interactions, psychological well-being, side effects of treatment, and the patient's perception of the disease itself (3).

Hemodialysis patients face unique challenges in maintaining their quality of life. They not only struggle with chronic health issues associated with kidney failure but also must manage the demanding nature of time-consuming therapy sessions. The increased attention given to quality of life is evident from the growing number of research studies devoted to its exploration, considering it a significant predictor of mortality and morbidity (4, 5).

Despite global concern for improving the quality of life of chronic patients, the prevalence of depression, anxiety, and sleep disorders is constantly increasing compared to the general population (6). The COVID-19 pandemic affected millions of people worldwide, and the hemodialysis population was one of the most affected. Anxiety, defined as an affective state characterized by psychomotor restlessness, indistinct fear, and no discernible object, is growing worldwide and among hemodialysis patients (7). It is important to note that the relationship between anxiety and quality of life is bidirectional. This means that while anxiety can have a negative impact on one's quality of life, factors such as social support, adaptation strategies, and access to mental health resources can also influence the experience and severity of anxiety symptoms (6).

COVID-19 infection, a severe respiratory infection caused by SARS-CoV-2, spread rapidly worldwide, leading the World Health Organization (WHO) to declare it a pandemic in March 2020. The pandemic affected millions of people worldwide, with a mortality rate in patients over 65 years of age of 34.5% (8). COVID-19 infection is caused by SARS-CoV-2, which belongs to the Beta coronaviruses (CoV) and manifests as severe respiratory syndrome. The outbreak originated in the Chinese city of Wuhan in December 2019 as an atypical viral pneumonia that quickly spread worldwide (9). Transmission occurred rapidly through direct contact with infected individuals, contact with contaminated surfaces or biological products (10, 11).

According to the December 2020 COVID-19 Weekly Epidemiological Update released by the World Health Organization (WHO), there were reported 79.2 million confirmed cases of COVID-19 and over 1.7 million deaths worldwide. While some patients were asymptomatic, others experienced a wide spectrum of symptoms such as fever, cough, myalgia, diarrhea, nausea, and anosmia, leading up to severe respiratory failure, septic shock, and multiple organ failure (10, 11).

Organic lesions were associated with a cytokine storm, vascular endothelium injury, and disseminated vascular coagulation, resulting in increased occurrences of strokes, myocardial infarctions, or pulmonary thromboembolisms (12).

The global pandemic has worsened social and economic challenges on a broad scale, and has additionally heightened preexisting psychosocial issues within this specific patient population (13). Displacements between home and dialysis centers, patient influx in confined spaces as well as interactions with medical staff have made hemodialysis patients, who have compromised immune systems, a vulnerable category for contracting COVID-19 (14).

The anxiety triggered by stressors related to COVID-19 includes apprehension regarding the contagious nature of the disease, financial instability, the loss of family members, friends, or colleagues, and the imposition of mandatory quarantine and social isolation. This is especially crucial for patients who already contend with heightened vulnerability due to elevated levels of physical and mental distress. In individuals undergoing dialysis, symptoms of depression and anxiety are prevalent and correlate with adverse clinical outcomes such as diminished quality of life, heightened rates of hospitalization, and increased mortality (15). Previous studies on epidemics have shown that the level of anxiety and depression in a group was much higher than the risk of contracting the disease (9). The attitude of hemodialysis patients towards the disease varies depending on their level of education, personal perception, family and surrounding support. Thus, the perception of the disease, dependence on the dialysis machine, dietary restrictions, comorbidities, and chronic pain are associated with restlessness, insecurity, and a sense of constraint due to limited mobility, all leading to reactive psychological suffering (16).

Anxiety, defined as an affective condition, is the emotion of fear that arises in stressful or threatening circumstances. It is a typical reaction to threat, but if it becomes excessive or lasts for a long time, it may be considered an anxiety disorder (10).

Unlike depression that has been extensively debated, anxiety has been less studied, although previous research showed that over 50% of hemodialysis patients with psychological impairment associate anxiety-depressive ailment (17). Anxiety and depression lead to sleep disorders, which over time develop into chronic fatigue (both mental and physical), deteriorating everyday life and exacerbating symptoms of depression and/or anxiety, thereby entering a vicious circle (18,19). Consequently, anxiety and depression remain associated with demographic, socio-economic and educational factors, with different prevalence rates depending on these factors (10).

Suceava was the first region in Romania seriously affected by COVID-19, with the first and most severe restrictions imposed. The dialysis population was one of the most affected categories of chronic disease patients during the pandemic, which is why we wanted to evaluate the impact of the first wave of COVID-19 among this population.

MATERIALS AND METHODS

In the current study, all 102 patients included were enrolled in the chronic hemodialysis program at AVITUM-BBRAUN Suceava. The study was conducted with the approval of the ethics committee of the "Grigore T. Popa" University of Medicine and Pharmacy of Iasi and the ethics committee of Avitum Romania (since late 2019).

All patients included in the analysis completed the Kidney-Disease and Quality of Life (KDQOL™-36) questionnaire. Dialysis centers currently use the KDQOL-36 tool to evaluate diverse facets of patients' quality of life throughout their dialysis treatment. The insights gleaned from responses to KDQOL-36 scales are subsequently utilized to customize individualized care plans for each dialysis patient. The evaluation questionnaire used in our study aimed to assess the impact of COVID-19 on various areas, including physical Score, pain intensity, daily activity, social functionality, mental health com-

ponent, sleep quality, social support, patient satisfaction with medical care, and anxiety. All patients completed the questionnaire during their dialysis sessions.

Microsoft Office Excel/Word 2013 and IBM *SPSS Statistics 25.0* were used for the statistical analysis. The Shapiro-Wilk test was used to determine the distribution of quantitative data, which were then displayed as means with standard deviations or as medians with interpercentile intervals. Using the Mann-Whitney U test, independent quantitative variables with non-parametric distributions were examined. Depending on the equality of variances shown by the Levene test, independent quantitative variables with normal distribution were evaluated using either the Student' t-test or the Welch's t-test. When assessing correlations between quantitative variables, non-parametric variables were correlated using Spearman's rho correlation coefficients, while normal distribution variables were correlated using Pearson correlation coefficients.

RESULTS

The fist table embodies parameters related to physical functioning, emotional well-being, daily activity performance, and social interactions. Each of the KDQOL-36 kidney-specific scales is Scored by transforming all items linearly to a range of 0–100 and then averaging the Scores. The results are presented with its mean ± standard deviation and median (with interquartile range), minimum and maximum deviation average.

TABLE I.

KDQOL-36 Assessment Scores

Parameter	Mean ± SD	Median (IQR)	Min	Max
Score-PF	50 ± 22.04	55 (35-65)	0	90
Score-RP	46.57 ± 45.6	50 (0-100)	0	100
Score-BP	50.49 ± 21.91	55 (42.5-67.5)	0	100
Score-GH	22.16 ± 10.35	25 (15-30)	0	40
Score-PCS	42.3 ± 19.56	43.75(29.21-60)	0	76.3
Score-VT	37.74 ± 16.17	40 (30-50)	0	65
Score-SF	51.47 ± 21.49	50 (37.5-62.5)	0	100
Score-RE	47.05 ± 42.04	33.3 (0-100)	0	100
Score-MH	51.92 ± 13.7	56 (48-60)	4	68
Score-MCS	47.04 ± 18.91	50.62 (35.14-62.28)	1	80
Score-CKD Symptoms	83.25 ± 13.67	85.41 (79.16-92.18)	29.2	100
Score-CKD Effects	60.43 ± 12.67	60.71 (53.57-71.42)	21.4	82.1
Score-Weight CKD	29.22 ± 13.79	31.25 (18.75-37.5)	0	50
Score-status career	45.09 ± 14.94	50 (50-50)	0	50
Score-Sleep	58.62 ± 15.84	62.5 (55-67.5)	7.5	85
Score-social support	88.88 ± 12.03	83.33 (83.33-100)	66.7	100
Score-dialysis support	94.6 ± 8.15	100 (87.5-100)	75	100
Score-patient satisfaction	95.26 ± 7.91	100 (83.33-100)	66.7	100
Score-KDCS	69.42 ± 6.79	70.71 (65.9-75)	45	79.3

PF- Physical Functioning Score; RP- Role Physical Score; BP- Bodily Pain Score; GH- General Health; PCS- Physical Component Score; VT- Vitality Score; SF- Social Functioning; RE-Role-Emotional; MH-Mental Health; MCS-Mental Component Summary; CKD- Chronic Kidney Disease; KDCS- Kidney Disease Composite Score.

The findings indicate low scores in physical functioning, emotional well-being and increased levels of sleep disturbances and pain. Conversely, the evidences demonstrate strong social support, high level of patient satisfaction with medical care and support (patient satisfaction and dialysis support), and positive mental health.

Score_MH (p<0.001**) x Score_KDCS (p<0.001**)	<0.001, R=0.357
Score_MCS (p=0.001**) x Score_Sleep (p<0.001**)	0.002, R=0.302
Score_MCS (p=0.001**) x Score_KDCS (p<0.001**)	0.004, R=0.282
Score_EffectsCKD (p=0.001**) x Score_Sleep (p<0.001**)	0.003, R=0.288

BP- Bodily Pain Score; GH- General Health; PCS- Physical Component Score; MH-Mental Health; MCS-Mental Component Summary; CKD- Chronic Kidney Disease; KDCS- Kidney Disease Composite Score.

Table II depicts the correlation between various aspects of quality of life and chronic kidney disease. Each correlation is indicated by the Pearson correlation coefficient (R) along with its corresponding p-value. The p-values are denoted as significant (**p<0.001) or marginally significant (*p=0.001). These correlations provide insights into how various aspects of quality of life are interrelated in the context of chronic kidney disease.

The correlation between Score BP (bodily pain) and Score GH (general health) is highly significant (p<0.001) with a correlation coefficient (R) of 0.345, indicating a moderate positive correlation between blood pressure and general health. Similarly, each correlation entry in the table provides insights into the strength and significance of the relationship between different aspects of quality of life and chronic kidney disease.

The strength of the correlation is interpreted based on the magnitude of the correlation coefficient (R), where values closer to 1 indicate a stronger correlation, with positive values indicating a positive relationship and negative values indicating a negative relationship**.**

The correlation between Score GH and Score MH has an R-value of 0.563, indicating a relatively stronger positive association between general health and mental health (tab. II).

On the other hand, correlations such as Score MCS and Score Sleep have R-values of 0.302, suggesting a weaker positive relationship between mental health and sleep quality. The significant positive correlations observed between Score BP and other parameters such as Score GH, Score MH, Score MCS, and Score Sleep indicate an association between higher levels of bodily pain and poorer general health, mental health, and sleep quality.

DISCUSSION

The study investigated the impact of the COVID-19 pandemic on the health-related quality of life and physical activity levels of individuals undergoing hemodialysis. It involved 102 hemodialysis patients surveyed in October 2020. Descriptively, the findings revealed an increase in anxiety, perception of pain, and sleep disturbances, contributing to an overall low quality of life score among the participants. In line with previous research, the study found that physical functioning was significantly reduced in hemodialysis patients compared to the general population. This observation remained consistent with the findings of other studies (20).

The average age of the participants in the examined group was 57.28 years, with a standard deviation of ±13.23 years. Patients undergoing hemodialysis frequently experience fatigue and weakness during and after their dialysis sessions, which can persist between treatments and hinder their ability to engage in daily activities and exercise (21). Additionally, individuals undergoing hemodialysis commonly experience bone mineral disorders, which increase the risk of bone fractures, bone pain, and osteoporosis. These conditions can restrict mobility, elevate the risk of falls and fractures, and consequently impact physical functioning (22). Moreover, peripheral neuropathy, characterized by sensory disturbances (such as numbness or tingling) and motor deficits in the extremities (weakness or loss of coordination), can further compromise balance, coordination, and mobility, thereby affecting physical functioning and increasing the risk of falls.

The current study reveals that the physical condition of hemodialysis patients is reduced by half compared to normal levels, a finding consistent with previous research (19).

Despite variations in prevalence and perception among hemodialysis patients, the intensity of pain remains high, as observed in our survey. Pain experienced by these individuals can arise from various sources, including vascular access sites, musculoskeletal issues, muscle cramps, discomfort from prolonged immobility, and neuropathic conditions. Factors such as diabetes, vitamin deficiencies, osteoporosis (21) and uremic toxins can exacerbate pain symptoms (22). Notably, numerous studies have demonstrated a significant relationship between a low pain index and psycho-emotional balance, indicating similar be-

havioral patterns between the two (23).

The COVID-19 pandemic significantly disrupted the daily activities of the patients under study, aligning with findings from prior research, primarily attributed to imposed isolation and restrictions (24). Among HD subjects, a notable correlation exists between increased mortality rates and self-reported low levels of physical function. This association is compounded by the observation that HD patients are considerably more sedentary compared to other inactive populations.

Literature research indicates that HD patients classified as sedentary, face a more than 60% higher risk of mortality annually than those who engage in regular physical activity. Enhancing muscle strength represents a potentially beneficial factor for HD patients (25), achievable through the incorporation of progressive resistance training into their exercise regimens. Despite the significant link between physical function and outcomes for HD patients, such as mortality, objective measures of physical function are underutilized.

Our results did not indicate an impact upon the enrolled subjects' careers, as the sensitive majority were not employed, consistent with findings from other studies (26). The thrice-weekly dialysis program, along with the lengthy four-hour sessions and the logistics of commuting between home and the dialysis center, influence and often restrict patients' ability to maintain employment; this might be one of the most reasonable explanations regarding their job-free status. Moreover, it is worthy to mention that during the pandemic, patients largely relied on sickness benefits, disability pensions, and social support without experiencing significant income impacts.

The study findings revealed an increase in sleep disorders during the pandemic, in line with previous research (26). Sleep plays a vital role in supporting immune function, metabolism, and cardiovascular health. Insomnia, a common sleep disorder characterized by difficulty in falling or staying asleep, or non-restorative sleep, is closely linked to the onset and exacerbation of mental health issues such as depression, anxiety, and mood disorders. Chronic sleep disturbances can contribute to mood and emotional disorders, resulting in heightened irritability, stress, and emotional volatility. They can significantly diminish overall quality of life by affecting physical health, mental well-being, and social functioning (27).

Insomnia is prevalent among hemodialysis patients, with contributing factors including pain, discomfort during dialysis, restless legs syndrome, anxiety, depression, medication side effects, obesity-related sleep apnea, and fluid overload (28, 29). During the COVID-19 pandemic, sleep disorders among hemodialysis patients have become an even more pressing concern due to added stressors and disruptions in routine healthcare services, including night shifts for COVID - positive patients. Consequently, there has been a disturbance of the circadian rhythm, the internal clock of the body that regulates sleep-wake cycles (30).

The study results indicate an elevated level of patient satisfaction regarding the quality of medical care and support from medical staff during the pandemic, consistent with findings from other studies. (31). Satisfaction is often subjective and influenced by personal preferences, values, and expectations. It reflects an individual's

perception of the extent to which their needs, desires, and goals are met across various aspects of their lives (32).

The increased satisfaction observed in our study can be attributed to the safety measures implemented in dialysis centers, including screening protocols, the use of personal protective equipment, infection control practices, and effective communication between medical staff and patients. These measures, along with the support provided and the individualized approach to meeting each patient's needs by the medical staff from AVITUM-BBRAUN Suceava, Romania, contributed to the augmented satisfaction levels.

In our study, we observed a notable elevation in the level of social support among the participants. This finding suggests a positive trend towards enhanced social networks and interpersonal connections within the studied population. Such an increase in social support may play a crucial role in buffering against the negative effects of stress and adversity, potentially contributing to improved overall well-being and resilience among individuals facing health challenges. Further analysis and exploration of the mechanisms underlying this observed increase in social support could provide valuable insights into the factors influencing social dynamics and support systems within this context. These results align with most studies indicating that social support is crucial for maintaining mental health and a good quality of life. Studies conducted in Ethiopia and the USA among dialysis patients of various races have pointed out that limited social support is associated with reduced quality of life and emotional imbalance (32, 33).

Constantly worrying about the possibility of contracting the disease leads to hypervigilance regarding symptoms, excessive hand washing, and avoidance of situations or places perceived as risky. The overall perceived stress score was found to be significantly higher in the HD patient group. It is possible that the need for regular treatment at a dialysis center, along with the inability to adhere to quarantine or social distancing recommendations, played a role in the high level of anxiety observed among patients undergoing HD. Previous studies have also reported elevated levels of anxiety during the pandemic, which may stem from fears of infection, social isolation, physical distancing measures, and economic challenges (34). In this context, the study's findings revealed an extensive level of anxiety among the participants, which aligns with findings from some previous studies (35, 36).

Death anxiety can be described as a feeling of worry, irritability, or fear stemming from awareness of a real or perceived threat to one's existence. Patients undergoing dialysis, who rely on the treatment to sustain their lives, often experience a shortened quality of life and a reduced life expectancy, which can contribute to death anxiety.

Despite the fact that hemodialysis therapy has improved survival rates, grappling with a serious health condition can exacerbate feelings of death anxiety. Moreover, given its association with various psychological disorders, death anxiety represents a significant psychological symptom that warrants attention.

Anxiety related to the coronavirus pandemic, often referred to as coronavirus-generated anxiety, pertains to instances of dysfunctional anxiety triggered by the

COVID-19 pandemic. Research conducted on the general population during the pandemic has indicated that heightened levels of anxiety related to COVID-19 can trigger severe psychological issues (37, 38, 39).

The region where the study was carried out, Suceava county, was particularly hard-hit by the pandemic, which may account for the expanded degree of anxiety observed among the participants.

Concerns about contracting the infection, especially given their underlying health conditions, as well as apprehensions about virus transmission within the dialysis unit, likely contributed to this heightened anxiety.

The COVID-19 pandemic has introduced significant challenges for hemodialysis patients, exacerbating existing difficulties and introducing new stressors that have had a profound impact on their health, well-being, and quality of life.

The current study revealed that patients experienced worsened sleep disorders and increased pain intensity, both of which had significant implications for their overall quality of life.

Recognizing and addressing sleep disorders through targeted interventions and interdisciplinary collaboration are crucial steps toward improving sleep quality and optimizing outcomes related to insomnia within this population.

Moreover, individuals with higher levels of education may exhibit greater self-confidence and self-control, potentially leading to better treatment adherence. With a more extensive health education, these individuals may possess a better understanding of their treatment and health, which could encourage them to more effectively adhere to medical guidelines.

The connection between educational attainment and psychosocial factors, such as stress and coping skills, alongside treatment adherence, is likely multifaceted and complex.

In conclusion, chronic kidney disease profoundly impacts the daily lives of affected patients, affecting not only physical health but also emotional well-being and quality of life.

Considering that new research indicates that many patients place a higher priority on life-quality outcomes - like physical independence - than on longevity, it is reasonable to conclude that providing adequate support and care to patients with chronic kidney disease is crucial for effectively managing the condition and maximizing their quality of life.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest and they received no funding.

EVALUATION OF THE QUALITY OF PROFESSIONAL LIFE OF MEDICAL STAFF IN THREE EMERGENCY MEDICINE UNITS FROM ROMANIA (Abstract): Understanding the professional quality of life of medical staff and its determinants is essential for addressing significant issues in this area. A preliminary study is necessary to identify organizational weaknesses and strengths, with the ultimate goal of enhancing healthcare services and their quality. Given its impact on service quality, the professional quality of life of medical staff is a critical concern for healthcare organizations. This study **aimed** to evaluate the professional quality of life of medical staff, presenting and critically assessing the available evidence on the overall professional quality of life of medical personnel in three emergency medical units in Romania. **Materials and methods**: To evaluate the professional quality of life of medical staff in emergency medicine units, a study was conducted from September 1, 2023, to September 30, 2023. The research took place in three emergency units in Romania: "Sf. Spiridon" County Clinical Emergency Hospital from Iasi, "Sf. Ioan cel Nou" County Emergency Hospital from Suceava and the Inspectorates for Emergency Situations (IES) from Iasi and Suceava Counties (IES). **Results**: Three groups of employees representing medical personnel from three emergency medicine units in Romania were analyzed. They are represented by 42 doctors (47.73%), 32 nurses (36.36%) and 14 workers in the Inspectorate for Emergency Situations (IESw) (15.91%). The average age of the study participants was 36.4± 8.41 years. The results indicate the mean values of the sub scores for the ProQOL subscales: compassion satisfaction, burnout and secondary traumatic stress. These were compared between the three groups according to profession (physician, nurse, IES workers). Significant differences in their mean ProQOL subscale scores were noted. **Conclusions**: Although physicians, nurses, and IES workers share many professional experiences, significant differences arise from their specific roles, work environments, and the unique stresses they encounter. Recognizing these differences is crucial for addressing their distinct needs and effectively supporting their well-being. **Keywords**: PROQOL, EMERGENCY MEDICINE UNITS, MEDICAL STAFF, BURNOUT, COMPASSION SATISFACTION, SECONDARY TRAUMATIC STRESS.

INTRODUCTION

Burnout syndrome, recognized by the WHO as a work-related disease, arises from chronic stress (1). It typically develops in high-pressure environments, with unstable work schedules, shifts, and overnight work (2, 3). This condition negatively impacts the mental and physical health of workers, particularly healthcare professionals (4). Burnout is characterized by three main components: emotional exhaustion, depersonalization, and low personal accomplishment (5).

Job satisfaction, perception of professional life, and professional quality of life collectively define the quality of professional life (6). This quality significantly impacts health services and the overall efficacy of any healthcare process. The professional quality of life of healthcare workers directly influences the quality of care provided and patient satisfaction, making it essential to consider the satisfaction of these workers. Assessing professional quality of life helps identify organizational strengths and weaknesses (7). Research indicates that implementing practices to enhance professional quality of life benefits institutions, healthcare workers, and patients alike (8, 9). Therefore, healthcare organizations must measure and address professional quality of life to improve care quality and patient satisfaction (10).

Professional quality of life is a complex, multidimensional concept shaped by personal feelings and perceptions. Factors determining this quality include management practices, relationships with colleagues, demographic characteristics, workload, job promotion opportunities, salary and rewards, and autonomy (11).

The significance of professional quality of life lies in its impact on health services and care quality (12). The relationship between professional quality of life and outcomes in professional practice is well established. While this area has been extensively studied among healthcare workers, research on nurses in emergency medicine units remains limited (13). Factors influencing professional quality of life encompass individual, social, environmental, contextual, operational, and administrative elements, as well as external factors like patient demands, healthcare policies, and the labor market (14, 15). Specific factors for emergency medicine staff include salary, workload, and educational satisfaction, and work environment, relationships with colleagues, demographic characteristics, shift work, and management style (16).

The growing shortage of medical staff has increased the responsibilities of nurses and doctors. Despite their critical role in prevention and health promotion, there is limited evidence regarding their professional quality of life (17). Identifying the professional quality of life of medical staff and the associated determinants can address major issues in this area. A preliminary study is necessary to overcome organizational weaknesses and highlight strengths, ultimately aiming to improve healthcare services and their quality (18).

The professional quality of life of medical staff is a crucial issue that healthcare organizations must examine due to its influence on service quality.

This study aimed to evaluate the professional quality of life of medical staff. It seeks to present and critically assess the available evidence on the overall professional quality of life of medical personnel in three emergency medical units in Romania.

MATERIALS AND METHODS

In order to evaluate the quality of the

professional life of medical staff in emergency medicine units, a study was carried out between September 1st, 2023 and September 30th, 2023. The research was carried out in three emergency units in Romania: "Sf. Spiridon" County Clinical Emergency Hospital from Iasi, "Sf. Ioan cel Nou" County Emergency Hospital from Suceava and the Inspectorates for Emergency Situations (IES) from Iasi and Suceava Counties.

The study used the Professional Quality of Life (ProQoL) questionnaire as a data collection tool (19). This questionnaire (ProQOL) comprises 30 items with a 5-point Likert scale (1 = Never, 2 = Rarely, 3 = Sometimes, 4 = Often, 5 = Very often) and is composed of three subscales: compassion/satisfaction (10 items), burnout (10 items) and secondary traumatic stress (10 items).

Compassion/satisfaction items describe the positive aspects of helping work ("I get satisfaction from being able to help people"), as opposed to burnout ("I feel trapped in my work as a helper") and secondarily traumatic stress ("I think that the traumatic stress of those I help may have affected me as well") (19).

Respondents were instructed to indicate how often they had experienced each item in the past 30 days. Questionnaires were scored by summing item responses for each 10-item subscale, with higher scores indicating higher levels of compassion satisfaction, posttraumatic stress, and exhaustion. The scores from each of the subscales can be classified into compassion satisfaction, burnout and secondary traumatic stress: < 22 low; 23–41 medium; > 42 height.

The Romanian version of the ProQOL for the current study has a Cronbach's alpha coefficient (assessment of the internal consistency of the questionnaire) of 0.82 for compassion satisfaction, 0.78 for secondary traumatic stress and 0.87 for burnout.

The statistical analysis of the data was conducted using the *SPSS version 29.0* software package. Descriptive statistics were calculated for the analyzed variables. Continuous variables were reported as mean values with standard deviation (SD). The Kolmogorov-Smirnov test was used to verify the normal distribution of the variables. Qualitative variables were presented as absolute counts (n) and relative frequencies (%). Group comparisons were performed using the Pearson chi-square test and the Kruskal-Wallis test. A significance level (p-value) of less than 0.05 was considered statistically significant.

RESULTS

Three groups of employees representing medical personnel from three emergency medicine units in Romania were analyzed. They were represented by 42 doctors (47.73%), 32 nurses (36.36%) and 14 workers in the Inspectorate for Emergency Situations (IESw) (15.91%). The average age of the study participants was 36.4± 8.41 years (mean ± standard deviation).

Study participants were informed about the purpose and content of the questionnaire. They were told the following: "The ProQOL questionnaire assesses how you deal with various difficult, stressful situations at work. By difficult situations, we mean the following: exposure to a situation whereby a person is faced with an event involving death or the threat of death, serious injury, injury or a threat to physical well-being. So, we are interested in the extent to which interacting with patients with different problems affects your personal life, positively or negatively. Re-

search shows that a human connection is made between the medical setting and the patient, even if the patient is not a well-known person, and this connection can influence your way of being. Please evaluate each statement in the first part by referring to your experiences at work, not your personal life. Also, when thinking about stressful experiences, consider the definition given above, that is, stress caused by dealing with patient difficulties, not by your collegial relationships or other aspects of the workplace."

The Professional Quality of Life (ProQOL) scale measures the positive and negative aspects of working in helping professions, encompassing compassion satisfaction, burnout, and secondary traumatic stress. The analysis assessed significant differences occurring between physicians, nurses, and Intensive Emergency Services (IES) workers on specific items of the ProQOL questionnaire. Significant differences were noted between the following items 1, 5, 6, 9, 11, 12, 21, 22, 24, 25, 28, 29 and 30 (tab. I).

1. "I am in a good mood most of the time."

Physicians often experience high levels of stress due to their extensive responsibilities and the critical nature of their decisions. Their mood may be more variable compared to nurses and IES workers, influenced by the pressure of making life-or-death decisions. Nurses, while also under stress, may have more direct patient interaction, which can provide emotional rewards that boost mood. However, their mood can still be negatively impacted by the emotional labor of care giving.

IES workers often face the most acute stress due to the unpredictable and high-stakes nature of emergency services. Their mood might fluctuate significantly, often swaying between the adrenaline rush of successful interventions and the lows of witnessing trauma.

5. "I flinch or get scared when I hear different unexpected sounds."

Physicians typically work in more controlled environments where unexpected sounds are less frequent, possibly making them less likely to flinch compared to IES workers. However, the constant beeping of monitors and alarms can still be startling. Nurses are often in bustling environments with frequent alarms and calls, potentially desensitizing them to sudden noises, but prolonged exposure can still lead to heightened startle responses. IES workers are most exposed to unexpected, loud, and often distressing sounds. Their work environment predisposes them to higher startle responses due to the nature of emergencies and the need for rapid, responsive action.

6. "I feel that I still have energy after a day of working with people I help."

Physicians may experience significant mental fatigue due to the intensity of their decision-making processes and long working hours, leaving them with little energy at the end of the day. Nurses might have varying levels of energy post-shift. Physical exhaustion is common due to the demanding nature of their tasks, but emotional fulfillment from patient interaction can sometimes counterbalance this fatigue. IES workers are likely to be the most drained, both physically and mentally, after a day of responding to emergencies. The high-stress environment and physical demands of their job often leave them exhausted.

9. "I think that it is possible to be affected by the stressful situations of the people I work with."

Physicians are often required to main-

tain a level of detachment to make objective decisions, but the cumulative effect of patient stress and critical cases can significantly impact them over time. Nurses are more likely to develop close emotional bonds with patients, making them more susceptible to being affected by the stressful situations their patients endure. IES workers face the rawest and most acute forms of stress. The intensity and immediacy of emergencies can profoundly affect them, given the life-and-death situations they frequently encounter.

11. "Because of the nature of my work, I feel that different things annoy me."

Physicians might experience annoyance stemming from systemic issues, administrative tasks, or the high expectations placed on them. Nurses often face the brunt of operational inefficiencies, staff shortages, and demanding patient care routines, contributing to frequent annoyances. IES workers deal with high-stress situations where any small operational hiccup or miscommunication can lead to significant annoyance due to the potential consequences.

12. "I like the work I do (the situation of providing specialized support)."

Physicians generally have high levels of job satisfaction from providing specialized medical care and making significant impacts on patient health. Nurses often derive satisfaction from their direct patient care roles and the ability to provide comfort and support, which is a core aspect of their job. IES workers find gratification in the immediacy and impact of their interventions, though the high-stress nature of their work can sometimes overshadow this satisfaction.

21. "I feel overwhelmed because the tasks I have seem endless."

Physicians may feel overwhelmed due to the combination of patient care, administrative responsibilities, and continuous professional development requirements. Nurses often experience a similar sense of being overwhelmed due to understaffing, high patient-to-nurse ratios, and extensive care giving duties. IES workers face overwhelming situations due to the unpredictable nature of emergencies and the continuous demand for their services without much respite.

22. "I believe that through my work I am useful to society."

Physicians typically have a strong sense of societal contribution through their ability to treat and cure illnesses. Nurses also feel highly useful to society, given their essential role in patient care and recovery. IES workers often perceive their work as highly impactful, given their role in saving lives and providing critical emergency care.

24. "I am proud of what I can do for those around me."

Physicians have a deep sense of pride in their ability to diagnose and treat complex medical conditions, often reflecting years of specialized training. Nurses take pride in their hands-on care and the personal connections they build with patients, often seeing the direct impact of their work on patient recovery. IES workers have immense pride in their ability to respond effectively in high-pressure situations and make a tangible difference in emergencies.

25. "As a result of work activities, some times I have thoughts that scare me."

Physicians might experience distressing thoughts due to the high-stakes nature of their decisions and the potential for adverse patient outcomes. Nurses can be haunted by the emotional burden of patient suffering and loss, leading to distressing thoughts.

IES workers are the most likely to have frightening thoughts due to the traumatic and often life-threatening situations they encounter regularly.

28. "I can't remember important parts of my professional activity with victims of traumatic events."

Physicians might struggle with memory issues due to cognitive overload and the vast amount of information they must process daily. Nurses can experience memory lapses due to the high emotional and physical demands of their job, especially when dealing with traumatic patient cases. IES workers are prone to memory issues as a coping mechanism to manage the intense stress and trauma associated with their work.

29. "I am a caring person."

Physicians often display care through their dedication to patient outcomes and the extensive effort they put into their work. Nurses are frequently seen as the epitome of caring in the healthcare system, given their close and continuous interaction with patients. IES workers demonstrate care through their rapid, life-saving actions and commitment to providing emergency assistance.

30. "I am satisfied that I chose this profession."

Physicians generally feel satisfied with their profession due to the respect, financial rewards, and the intellectual stimulation it provides. Nurses may find satisfaction in the personal fulfillment derived from patient care and the intrinsic rewards of their care giving role. IES workers often feel a profound sense of purpose and satisfaction from the immediate and visible impact of their work, despite the high stress involved.

TABLE I.

Comparative evaluation of the ProQOL questionnaire according to the profession of study participants

Professional Quality of Life Scale Items			**Physician (n=42)**	**Nurse (n=32)**	**IES workers (n=14)**	**p-value**
Age, years, mean (SD)			33.1 (7.78)	39.8 (9.02)	38.4 (4.48)	0.001
Gender, male / female, n (%)			8/34 (19.05/80.95)	10/22 (31.25/68.75)	14/0 (100/0)	<0.001
	Never	**Rarely**	**Sometimes**	**Often**	**Very often**	**p-value**
1. I am in a good mood most of the time.						
Physician / Nurse / IESw	0/1/0 (0/3.13/0)	1/0/0 (2.38/0/0)	15/3/2 (35.71/9.38/14.29)	14/19/3 (33.33/59.38/21.43)	12/9/9 (28.57/28.13/64.29)	0.0218*
2. I try to help as many people as I can with the time I have.						
Physician / Nurse / IESw	-	1/0/0 (2.38/0/0)	4/1/1 (9.52/3.13/7.14)	16/16/1 (38.1/50/7.14)	21/15/12 (50/46.88/85.71)	0.1261
3. I feel fulfilled by the fact that I am able to help people.						
Physician / Nurse / IESw	-	0/1/0 (0/3.13/0)	4/0/1 (9.52/0/7.14)	20/11/3 47.62/34.38/21.43)	18/20/10 (42.86/62.5/71.43)	0.1754
4. I feel close to the people I interact with.						
Physician / Nurse / IESw	0/1/0 (0/3.13/0)	5/0/1 (11.9/0/7.14)	15/8/1 (35.71/25/7.14)	15/17/7 (35.71/53.13/50)	7/6/5 (16.67/18.75/35.71)	0.1484

Professional Quality of Life Scale Items			Physician (n=42)	Nurse (n=32)	IES workers (n=14)	p-value
5. I flinch or get scared when I hear different unexpected sounds.						
Physician / Nurse / IESw	15/17/7 (35.71/53.13/50)	9/8/2 (21.43/25/14.29)	9/4/0 (21.43/12.5/0)	7/1/5 (16.67/3.13/35.71)	2/2/0 (4.76/6.25/0)	0.0401*
6. I feel that I still have energy after a day of working with people I help.						
Physician / Nurse / IESw	5/6/1 (11.9/18.75/7.14)	14/3/3 (33.33/9.38/21.43)	12/6/2 (28.57/18.75/14.29)	5/15/4 (11.9/46.88/28.57)	6/2/4 (14.29/6.25/28.57)	0.0161*
7. I find it difficult to separate my personal life from my professional life.						
Physician / Nurse / IESw	10/17/6 (23.81/53.13/42.86)	17/6/4 (40.48/18.75/28.57)	9/7/1 (21.43/21.88/7.14)	4/1/1 (9.52/3.13/7.14)	2/1/2 (4.76/3.13/14.29)	0.1634
8. Sometimes I am not very efficient at work because I am affected by the difficult experiences of the people, I help.						
Physician / Nurse / IESw	11/19/8 (26.19/59.38/57.14)	14/4/2 (33.33/12.5/14.29)	12/5/0 (28.57/15.63/0)	4/3/2 (9.52/9.38/14.29)	1/1/2 (2.38/3.13/14.29)	0.2176
9. I think that it is possible to be affected by the stressful situations of the people I work with.						
Physician / Nurse / IESw	7/6/6 (16.67/18.75/42.86)	12/16/3 (28.57/50/21.43)	12/5/0 (28.57/15.63/0)	6/4/5 (14.29/12.5/35.71)	5/1/0 (11.9/3.13/0)	0.0197*
10. I am attracted to my job, to the situations where I can be helpful to others.						
Physician / Nurse / IESw	2/1/1 (4.76/3.13/7.14)	4/0/0 (9.52/0/0)	10/5/1 (23.81/15.63/7.14)	14/17/3 (33.33/53.13/21.43)	12/9/9 (28.57/28.13/64.29)	0.7944

Physician / Nurse / IESw	0/4/0 (0/12.5/0)	1/0/0 (2.38/0/0)	6/4/0 (14.29/12.5/0)	16/11/2 (38.1/34.38/14.29)	19/13/12 (45.24/40.63/85.71)	0.0396*
13. Sometimes I feel depressed because of the difficult experiences of the people I work with.						
Physician / Nurse / IESw	13/15/9 (30.95/46.88/64.29)	14/6/1 (33.33/18.75/7.14)	6/5/0 (14.29/15.63/0)	4/4/2 (9.52/12.5/14.29)	5/2/2 (11.9/6.25/14.29)	0.2769
14. I feel that sometimes I also experience the trauma that the people I help go through.						
Physician / Nurse / IESw	12/11/5 (28.57/34.38/35.71)	19/13/6 (45.24/40.63/42.86)	7/4/3 (16.67/12.5/21.43)	2/4/0 (4.76/12.5/0)	2/0/0 (4.76/0/0)	0.6691
15. I have certain principles that help me cope with the situations I face at work.						
Physician / Nurse / IES	1/1/0 (2.38/3.13/0)	3/4/0 (7.14/12.5/0)	8/3/1 (19.05/9.38/7.14)	19/23/4 (45.24/71.88/28.57)	11/1/9 (26.19/3.13/64.29)	0.0024*
16. I am satisfied with the way I manage to apply my knowledge and different techniques in order to provide help.						
Physician / Nurse / IESw	-	-	16/1/3 (38.1/3.13/21.43)	15/19/2 (35.71/59.38/14.29)	11/12/9 (26.19/37.5/64.29)	0.0006*
17. I can say that I have achieved what I always wanted.						
Physician / Nurse / IESw	-	2/0/1 (4.76/0/7.14)	11/3/0 (26.19/9.38/0)	14/15/6 (33.33/46.88/42.86)	15/14/7 (35.71/43.75/50)	0.1591

Professional Quality of Life Scale Items			Physician (n=42)	Nurse (n=32)	IES workers (n=14)	p-value
18. The work I do gives me a lot of satisfaction.						
Physician / Nurse / IES	1/0/0 (2.38/0/0)	2/0/0 (4.76/0/0)	13/4/1 (30.95/12.5/7.14)	15/13/3 (35.71/40.63/21.43)	11/15/10 (26.19/46.88/71.43)	0.0704
19. Sometimes, I feel exhausted as a result of interacting with different people in suffering.						
Physician / Nurse / IESw	3/8/7 (7.14/25/50)	12/10/2 (28.57/31.25/14.29)	10/7/1 (23.81/21.88/7.14)	8/3/2 (19.05/9.38/14.29)	9/4/2 (21.43/12.5/14.29)	0.0681
20. I have feelings of kindness and understanding for the people I help.						
Physician / Nurse / IESw	1/1/0 (2.38/3.13/0)	1/0/0 (2.38/0/0)	8/2/1 (19.05/6.25/7.14)	16/16/2 (38.1/50/14.29)	16/13/11 (38.1/40.63/78.57)	0.1727
21. I feel overwhelmed because the tasks I have seem endless.						
Physician / Nurse / IESw	2/14/7 (4.76/43.75/50)	9/9/2 (21.43/28.13/14.29)	14/2/1 (33.33/6.25/7.14)	11/4/3 (26.19/12.5/21.43)	6/3/1 (14.29/9.38/7.14)	0.0012*
22. I believe that through my work I am useful to society.						
Physician / Nurse / IES	0/0/2 (0/0/50)	0/0/10 (0/0/14.29)	18/5/39 (56.25/35.71/7.14)	14/9/36 (43.75/64.29/21.43)	32/14/88 (0/0/7.14)	0.0158*
23. I avoid certain activities or situations because they remind me of the unfortunate experiences of the people I help.						
Physician / Nurse / IESw	19/13/10 (45.24/40.63/71.43)	13/10/2 (30.95/31.25/14.29)	5/5/1 (11.9/15.63/7.14)	3/2/1 (7.14/6.25/7.14)	2/2/0 (4.76/6.25/0)	0.7929
24. I am proud of what I can do for those around me.						
Physician / Nurse / IESw	0/2/0 (0/6.25/0)	1/0/1 (2.38/0/7.14)	10/1/0 (23.81/3.13/0)	18/9/4 (42.86/28.13/28.57)	13/20/9 (30.95/62.5/64.29)	0.0101*
25. As a result of work activities, sometimes I have thoughts that scare me.						
Physician / Nurse / IESw	14/22/11 (33.33/68.75/78.57)	9/8/1 (21.43/25/7.14)	12/1/1 (28.57/3.13/7.14)	6/1/1 (14.29/3.13/7.14)	1/0/0 (2.38/0/0)	0.0117*
26. I feel "stuck" in the system I have entered.						
Physician / Nurse / IES	13/17/9 (30.95/53.13/64.29)	13/8/2 (30.95/25/14.29)	5/2/0 (11.9/6.25/0)	8/3/2 (19.05/9.38/14.29)	3/2/1 (7.14/6.25/7.14)	0.4448
27. I believe I have a successful career.						
Physician / Nurse / IES	3/2/1 (7.14/6.25/7.14)	5/1/0 (11.9/3.13/0)	15/4/2 (35.71/12.5/14.29)	13/13/4 (30.95/40.63/28.57)	6/12/7 (14.29/37.5/50)	0.0636
28. I can't remember important parts of my professional activity with victims of various traumatic events.						
Physician / Nurse / IESw	9/14/8 (21.43/43.75/57.14)	15/10/4 (35.71/31.25/28.57)	16/4/2 (38.1/12.5/14.29)	2/4/0 (4.76/12.5/0)	-	0.0385*
29. I am a caring person.						
Physician / Nurse / IESw	-	-	9/0/0 (21.43/0/0)	19/15/5 (45.24/46.88/35.71)	14/17/9 (33.33/53.13/64.29)	0.0112*
30. I am satisfied that I chose this profession.						
Physician / Nurse / IESw	2/0/0 (4.76/0/0)	1/0/0 (2.38/0/0)	10/0/1 (23.81/0/7.14)	12/4/2 (28.57/12.5/14.29)	17/28/11 (40.48/87.5/78.57)	0.0061*

Continuous variables were expressed as mean (standard deviation), the variables did have a normal distribution.
Categorical variables: number (%); IESw – Inspectorate for Emergency Situations workers
† Pearson chi-square test; § Kruskal-Wallis test / * Marked effects are significant at $p < 0.05$

The results presented in table II indicate the mean values of the subscores for the ProQOL subscales: compassion satisfaction, burnout and secondary traumatic stress. These were compared between the three groups according to profession (physician, nurse, IES workers). Significant differences in their mean ProQOL subscale scores were noted.

The subscore for Compassion Satisfaction was significantly higher for nurses and IES workers (p = 0.0005), and for the physician the subscores for burnout (p = 0.0018) and secondary traumatic stress (p = 0.0185) were significantly higher (tab. II, fig. 1).

TABLE II.

Statistical indicators of subscores for the three ProQOL subscales by profession

Professional Quality of Life Scale SCORE SUBSCALE	Physician (n=42)	Nurse (n=32)	IES workers (n=14)	*p*-value§
Compassion Satisfaction, mean (SD)	38.40 (6.43)	42.25 (3.32)	44.79 (5.66)	0.0005*
Burnout	25.40 (5.17)	22.06 (3.62)	20.64 (6.83)	0.0018*
Secondary Traumatic Stress	25.88 (6.57)	21.91 (5.43)	22.21 (7.15)	0.0185*

Continuous variables were expressed as mean ± standard deviation (SD); the variables did have a normal distribution.

* Marked effects are significant at p < 0.05 / § Kruskal-Wallis test

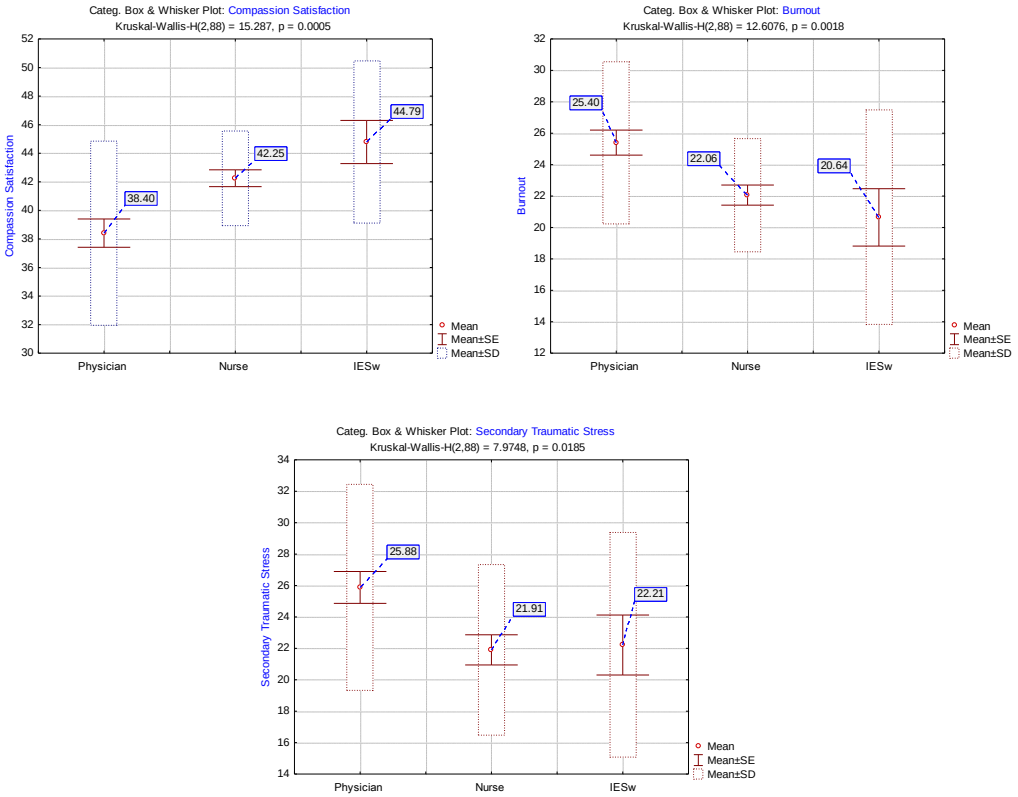

Fig. 1. Box and whisker plot for ProQOL subscores by profession

DISCUSSION

The Professional Quality of Life (ProQOL) scale assesses the positive and negative aspects of work in helping professions, focusing on compassion satisfaction, burnout, and secondary traumatic stress. This synthesis highlights the significant differences between physicians, nurses, and Intensive Emergency Services (IES) workers regarding specific items on the ProQOL questionnaire (19).

In the case of doctors, was noted a great mood variability, they are often mentally fatigued, less frequent startle response but affected by patient stress, they were also annoyed by systemic issues, high satisfaction from specialized care (20), overwhelmed by extensive responsibilities, with a strong sense of societal contribution, and pride in treating complex conditions, distressing thoughts from high-stakes decisions and memory issues from cognitive overload. Dedication to patient outcomes was generally satisfied with profession (21).

The nurses' mood was stimulated by the interaction with the patient despite the stress, there are mentioned a frequent physical exhaustion, some desensitization to sudden noises, but close bonds increase stress susceptibility. They were annoyed by operational inefficiencies, satisfaction from direct care, overwhelmed by high patient ratios, but felt highly useful, and proud of patient recovery. In this case emotional burden leaded to distressing thoughts and memory lapses (22).

Medical staff is often seen as the epitome of caring, finding deep fulfillment in their care giving roles. Their close and continuous interaction with patients allows them to provide comfort and support, which not only benefits the patients but also enhances the nurses' sense of professional satisfaction and personal accomplishment (23).

In the case of IES workers, significant mood changes were observed, being the most physically and mentally exhausted, highest startle response, profoundly impacted by acute stress. IES workers were annoyed by operational hiccups and gratification from impactful interventions. Overwhelmed by constant demand, they perceive work as highly impactful and immense pride in emergency response. IES workers often experience frequent frightening thoughts and may develop memory issues as a coping mechanism. Despite these challenges, they demonstrate their care through life-saving actions and maintain a profound sense of purpose, even under high stress (12, 24).

While all three groups-physicians, nurses, and IES workers-experience stress and derive satisfaction from their roles, the nature of their specific duties leads to significant differences in how they experience mood, energy, stress, job satisfaction, and professional pride. Understanding these differences is essential for providing tailored support to enhance their well-being and effectiveness in their respective roles (25, 26).

Hospital policies can be revised to address the root causes of physicians, nurses, and IES workers burnout syndrome. By allocating resources appropriately and conducting further research on effective prevention methods, hospitals can reduce the incidence of burnout among physicians, nurses, and IES workers. These measures will enhance the quality of workers from emergency medical units and lower turnover rates, which are essential for providing high-quality nursing care.

Workers from emergency medical units face significant challenges due to adverse working conditions. Factors such as workload overload, rotating shifts, low salaries, lack of autonomy, workplace violence, and bullying can lead to high emotional exhaustion, low accomplishment, and high deper-

sonalization (27). Additionally, lacking a partner can also contributes to these issues by depriving nurses of the security and support partners provide (17). These challenges can result in severe emotional problems, including insomnia, irritability, and stress (19). High burnout rates among nurses are associated with increased medication errors, higher infection rates, more patient falls, and lower quality of care (9, 16). Implementing spiritual interventions in the workplace may help mitigate these adverse outcomes (18). Variations in study results across countries may be due to differences in nurse-patient ratios and national medical systems' workloads (11). Furthermore, the imbalance between low salaries and high workloads significantly contributes to burnout (21). Increasing wages and reducing workloads could effectively address this issue. Differences in assessment tools also lead to varying results, as each scale has different criteria. Many nurses in the United States have considered leaving their jobs due to burnout (28). Despite these challenges, workers from emergency medical units are vital for achieving health-related goals, such as patient safety, managing non-communicable diseases, providing people-centered care, and ensuring universal health coverage (1). The prevalence of nursing burnout has been gradually increasing over the past decade, necessitating urgent attention.

CONCLUSIONS

In conclusion, while physicians, nurses, and IES workers share many similarities in their professional experiences, significant differences arise due to the nature of their specific roles, the environments they work in, and the unique stresses they face. Understanding these differences is crucial for addressing their distinct needs and supporting their well-being effectively.

While all three groups-physicians, nurses, and IES workers-experience stress and derive satisfaction from their roles, the nature of their specific duties leads to significant differences in how they experience mood, energy, stress, job satisfaction, and professional pride. Understanding these differences is essential for providing tailored support to enhance their well-being and effectiveness in their respective roles.

STATIC AND WHOLE-BODY IMAGES VS. SPECT: TOGETHER OR SEPARATE FOR AN ACCURATE DETECTION OF TRANSTHYRETIN CARDIAC AMYLOIDOSIS (Abstract): Transthyretin cardiac amyloidosis (ATTR-CA) is a protein deposition disease that represents a challenge to be diagnosed by the practicing physician. As the gold standard method is not widely available correlations between biomarkers, electrocardiography, echocardiography, bone scintigraphy and free light chain dosage has proven to be a reliable alternative. Bone scintigraphy represents the corner stone for ATTR-CA detection; however, some patients cannot undergo all the required images for an easy and accurate diagnosis. Therefore, the aim of this study is to determine the bare minimum images that can be performed for an accurate diagnosis. **Materials and methods:** 80 patients that met the inclusion criteria were evaluated throw bone scintigraphy. Acquired images included: whole body bone scan (early and delayed), static followed by Single Photon Emission Computed Tomography (SPECT), if possible, centered on the thorax. Images were interpreted by visual scoring and semiquantitative methods. **Results**: 20 patients were diagnosed with ATTR cardiac amyloidosis by visual scoring, however not all of them underwent all the necessary images. Semiquantitative methods results were above the established threshold and therefore sustained the visual score. Nevertheless, ratio results differed between static and SPECT images. **Conclusions**: Ideally all type of images should be acquired for this type of patients, however, we determined that a minimum of whole-body ± static centered on the thorax images interpreted throw visual scoring and semiquantitative analysis can be enough if SPECT is not possible for a reliable diagnosis. **Keywords**: WHOLE-BODY, STATIC, SPECT, ATTR-CA, VISUAL SCORING, SEMIQUANTITATIVE ANALYSIS.

Transthyretin cardiac amyloidosis (ATTR-CA) is a rare disease characterized by continuous and progressive deposition of amyloid at the myocardium level resulting in a thickening of both ventricles and inter-atrial-ventricular septum. Undiagnosed and therefore untreated, can be fatal to the patient. The mechanism behind it is based on misfolding the transthyretin protein (a plasma transport protein that circulates as a stable tetramer and transport thyroxin and retinol). ATTR-CA can be

classified as wild-type (ATTRwt) and hereditary or with mutation (ATTRm or ATTRh) (1, 2).

Diagnosing this rare disease has always represented a challenge for the practicing physician. The gold standard method, endomyocardial biopsy, has proven to be invasive and not widely available. Therefore, the European Society of Cardiology (ESC), has presented and alternative to this method, by correlating the electrocardiography, ultrasonography and bone scintigraphy characteristics. Nevertheless, screening for these patients, before reaching the actual methods for detection, is based on the so called "red flags" that offer a possible profile for the most likely ATTR-CA candidate (3). The final diagnosis for ATTR-CA is represented by bone scintigraphy, an imaging investigation technique that studies the biodistribution of a radiotracer at the skeletal level using bisphosphonates such as HDP (hydroxyethylene diphosphonate) which is mainly indicated in oncology, rheumatology, bone and joint infections, orthopedics, sports and traumatology, metabolic bone disease and pediatrics. Nevertheless, it is also indicated for detecting ATTR-CA Standard uptake mechanism for bone scan is based on the absorption to the surface of hydroxyapatite crystals and it is dependent on local bone vascularization and osteoblastic activity. However, in case of ATTR-CA the exact uptake mechanism is not completely elucidated and therefore a few theories that try to explain it have emerged that are based on the calcium level, microcalcification, the amount and type of fibrils involved (3-10).

The acquisition protocol according to the American Society of Nuclear Cardiology (ASNC) and European Association of Nuclear Medicine (EANM) practice points guideline is based on acquiring planar centered on the thorax (anterior, lateral and left anterior oblique) or whole body (WB) images, followed by SPECT centered on the thorax at 1 hour with optional acquisition at 3 hours after the iv administration of the radiotracer. Image processing and interpretation is based on the Perugini visual score that analysis the uptake of the myocardium and a semiquantitative analysis based on comparing the heart uptake with the uptake contralateral side (H/CL) and the rib (H/R). According to the ASNC practice points guide the threshold for H/CL ratio for ATTR positive patients should be over 1.5 on SPECT images at one hour. However, for comparing the heart to the rib uptake, the guide suggests a visual evaluation (11-13).

Therefore, a correct assessment of heart uptake using visual score and semiquantitative methods may represent a solution for a better and more accurate detection. Nevertheless, basing the ratio result only on SPECT images obtained at one hour may prove to be useful in patients that have a referral diagnosis of possible cardiac amyloidosis. For patients that have been accidentally diagnosed (different referral diagnosis), most likely the SPECT at one hour step was missed. As a result, the diagnosis was most likely based on the static images. The aim of this paper is to compare the visual score and the semiquantitative method of both static and SPECT centered on the thorax images in order to determine the bare minimum of images that can be acquired for an accurate diagnosis.

MATERIALS AND METHODS

The lot was comprised of patients from the Nuclear Medicine Laboratory of "Sf. Spiridon" County Clinical Emergency

Hospital Iasi archive (2015-2023) and was based on the following criteria: patients with a referral diagnosis of possible cardiac amyloidosis, ATTR positive patients after bone scintigraphy regardless of the referral diagnosis, ATTR positive patients that underwent both static and SPECT centered on the thorax images. The analysis was focused especially on the patients that had underwent both static and SPECT images.

The patients were required to sign an informed consent. All the protocols were approved by the Ethics Committee of both the "Grigore T. Popa" University of Medicine and Pharmacy Iasi, Romania and "Sf. Spiridon" County Clinical Emergency Hospital of Iasi.

Bone scintigraphy acquisition protocol include early and delayed whole body (WB) images, static centered on the thorax images early (WB unavailable) and delayed followed by SPECT centered in the thorax.

Images processing and interpretation relied on the Perugini visual score and a semiquantitative method based on ratios between different regions of interest (ROI). The ROI for the static images was made initial on the highest uptake region (from a visual point of view) of the heart muscle, without including the ribs and by using the "mirror" function it was projected on the contralateral side and placed consecutively first over one of the ribs and then between the ribs (contralateral). The ROIs made on the SPECT images were made in a similar fashion, with the initial ROI made over the heart and using the "mirror" function it was projected on the contralateral side. The ROIs in this case include the whole left ventricle and was made on the transverse and coronal incidences. However, the initial ROI over the heart was made on the slice which presented the maximum dimension of the heart and was maintained for all of the other slices. The ratio results were analyzed based on the following parameters (tab. I):

TABLE I.
Semiquantitative method results and interpretation (H=heart; R=rib; CL=contralateral)

Ratio	Result	Interpretation
H/R	> 1	Myocardial uptake greater than rib uptake
	< 1	Myocardial uptake lower than rib uptake
	1	Myocardial uptake similar to rib capture
H/CL	0 - 1.49	Absence/slight uptake of the radiopharmaceutical in the myocardium
	1.5 - 3	Moderate/increased uptake of the radiopharmaceutical in the myocardium

RESULTS

Out of 80 patients with referral diagnosis of possible cardiac amyloidosis only 20 were determined to be ATTR positive after bone scintigraphy. Due to the fact that the other patients presented visual scores and ratio result underneath the threshold they were classified as non-ATTR (n-ATTR) and required further investigations. Not all of the patients were able to undergo SPECT imaging, however, almost all underwent static centered on the thorax images and all of them made WB images. The patients that were accidentally diagnosed, presented only with WB images. Nevertheless, H/CL and H/R, were obtained regardless of the acquired images.

Visual Score

Visual score was determined on early and delayed images. Most of the early images were acquired only in patients that

presented a referral diagnosis of cardiac amyloidosis. Therefore, for patients that were accidentally diagnosed, this type of images was not acquired.

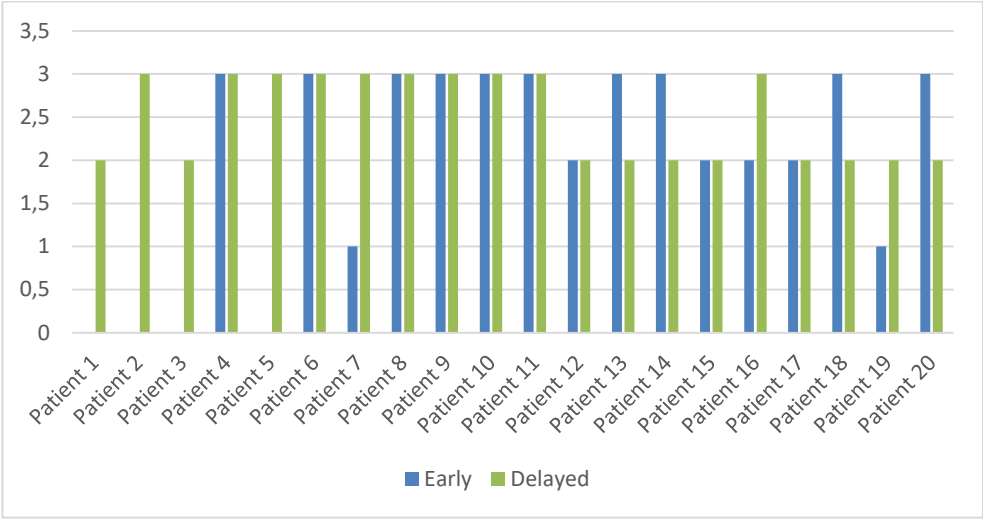

Fig 1. Visual Score of early and delayed images regarding for all 20 patients

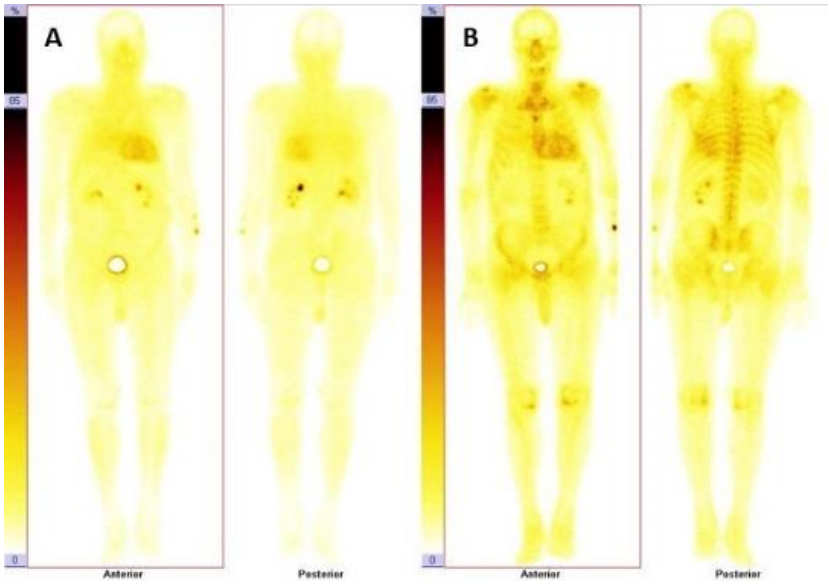
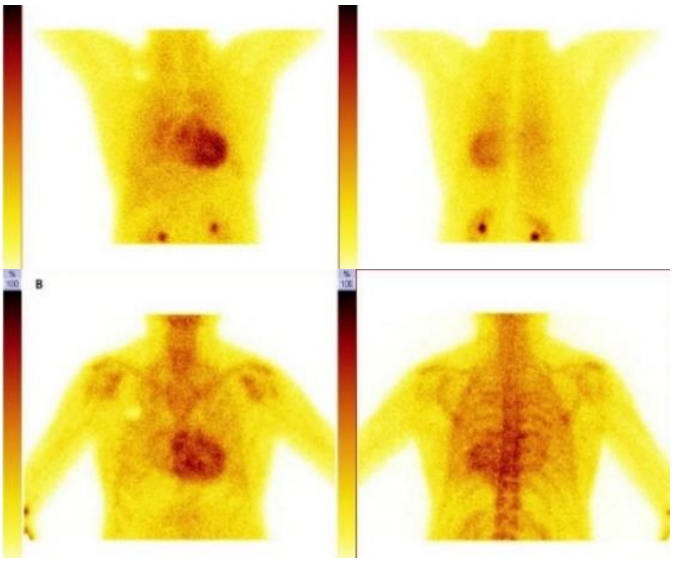
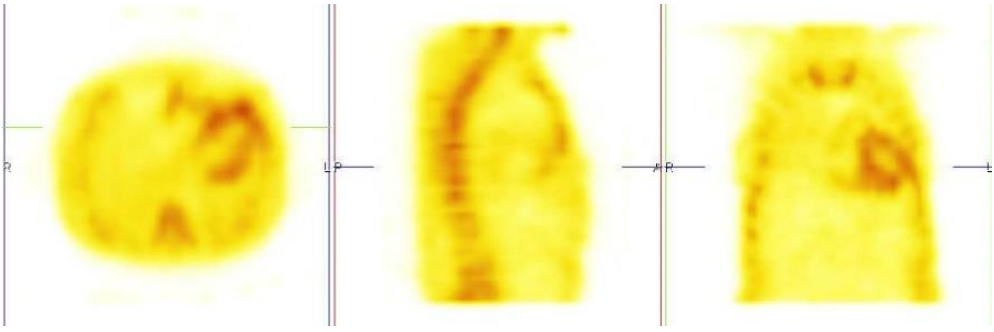
Visual scoring varied on early images, however, the aim of these images was to determine the location and dimension of the heart. Delayed images presented visual scoring typical for ATTR-CA (scores of 2 or 3).



CASE 1: 81 years old patient suspected of cardiac amyloidosis:
A. early WB images - visual score = 3; **B.** delayed WB images - visual score = 3



CASE 2: 52 years old patient suspected of cardiac amyloidosis: **A.** early static centered on the thorax - visual score = 3; **B.** delayed static centered on the thorax - visual score = 3



CASE 3: 82 years old patient suspected of cardiac amyloidosis: SPECT imaging reveals high visual uptake of the myocardium resulting in ATTR-CA

Fig 2. 3 Cases from our database - ATTR-CA positive patients determined by visual scoring Visual Scoring and Semiquantitative method

ATTR positive patients only with WB or Static images

The H/R and H/Cl ratios were performed on all of the patients that underwent bone scintigraphy and the visual score revealed a possible myocardium uptake. In accidental diagnosis in which only WB images were acquired, the ratios were performed only on those images, as static centered on the thorax were not acquired. Ratio results varied as follows: H/R: 0.9-2.08; H/Cl: 1.20-2.71. Nevertheless, in both cases, the ratio results were over the threshold and sustained the visual score.

The average of these ratio, demonstrated that the threshold of 1 for the H/R ratio and 1.5 for the H/Cl ratio represent, in association with the visual score as the bare mini-

mum for a possible diagnosis of ATTR-CA.

ATTR positive patients with WB/static and SPECT centered on the thorax images

The patients that underwent both WB/static and SPECT centered on the thorax, the ratio results differed slightly, but not to significant. In both image types, the H/R and H/Cl ratio results were over the determined threshold, therefore sustaining the visual score.

TABLE II.

Correlation between Delayed Visual Scoring and Semiquantitative Analysis on patients with WB/static and SPECT centered on the thorax images

	Visual scoring	H/R	H/CL		
	Delayed images	Static or WB	Static or WB	SPECT	
				Transvers	Coronal
Patient 4	3	1.68	2.09	2.13	2.50
Patient 6	3	1.56	1.75	1.82	1.82
Patient 7	3	2.06	2.41	2.97	2.98
Patient 11	3	1.67	1.60	2.37	2.98
Patient 13	2	1.64	1.81	2.11	1.79
Patient 14	2	1.88	2.07	2.80	2.94
Patient 15	2	1.66	1.72	1.88	1.57
Patient 16	3	1.77	2.08	2.71	2.25
Patient 17	2	1.42	2.12	1.61	1.75
Patient 18	2	1.08	1.54	2.90	2.11
Patient 19	2	1.19	1.65	2.30	1.80
Patient 20	2	1.18	1.63	1.81	2.06
AVERAGE Semiquantitative method results		1.57	1.87	2.28	2.19

By comparing the two semiquantitative methods it can be surmised that at least one ratio exceeds the established threshold. It can also be stated, that by comparing the H/CL made on the static images to those obtained on SPECT, the ratio results differ, in some cases. An explanation for this difference in the ratio result can be due to the type of images that were acquired. Static images are acquired in 2D, presenting the possibility of overlay, while SPECT presents a 3D image, reducing considerably the overlay factor. H/R ratio can only be made on static (2D) images therefore and therefore the ratio results are much lower compared to H/CL, but over the threshold in almost all of the patients. Furthermore, SPECT images offer a much clearer and with decreased background noise compared to static images. As a result, the ratios made on the SPECT images will present a higher result compared to those obtained on the static images.

Relying only on one ratio to sustain the visual score may prove to be inefficient (e.g. patients 18 - 20), as it can offer an equivocal result at best. By correlating both ratios made on static and SPECT images the additional information can offer a more accurate diagnosis.

DISCUSSION

ATTR-CA is a protein deposition disease located mainly in the myocardium. Diagnosing this rare pathology has proven to be difficult as, the gold standard method (endomyocardial biopsy) is not widely available. Therefore, alternative diagnostic

algorithms based on correlating different investigations have been utilized. As a result, nowadays, the main investigation used for ATTR-CA detection is bone scintigraphy, which has proven to be invaluable for this type of disease. The evaluation is based on myocardium uptake of the radiotracer. Standard acquired images include planar and SPECT centered on the thorax (WB images being considered only as an option) followed by visual evaluation of the uptake.

Our study aimed to determine if ATTR-CA diagnosis can be made on planar or WB images without necessarily using SPECT images even though it is recommended by the guidelines. Interpretation wise, we used visual scoring and semiquantitative methods based on H/CL made on both planar ± WB and SPECT and H/R made on planar ± WB. Due to the fact that some patients were discovered accidentally. As such, we compared the H/CL ratio result made on planar ± WB images to those obtained on SPECT images. In almost all of the cases the threshold on both image types was overcome. Due to the fact that planar images offer a 2D image of the patient, the problem of overlay should be taken into consideration and therefore, the ratio results could be lower than those obtained on SPECT, but still over the threshold. We also recorded cases in which the ratio result was close to the threshold, but didn't pass it on planar images compared to SPECT. In cases such as these, the H/R ration offered an additional parameter to the equation, that presented the possibility, along with the visual score, of ATTR-CA but in an early stage. In cases such as this, SPECT imaging could prove to be invaluable if the additional parameter didn't offer sufficient evidence to determine the diagnosis.

SPECT images offer a 3D image of the patient. The main advantage in these cases is the fact that the H/CL ratio result is much clearer in determining the presence of ATTR-CA than those obtained on planar images. However, in this type of images, H/R cannot be performed and as a consequence the result can be based only on visual scoring and H/CL region. Therefore, an additional parameter that could lighten the decision cannot be obtained on this type of image. Another disadvantage of this images refers to the dimension and position of the myocardium. If the myocardium is too large or if it's located to medial, it may be difficult to determine the H/CL region as the ROI made on the heart cannot be accurately mirrored to another region big enough or that doesn't include the myocardium to obtain a good result. In such cases, planar images may prove invaluable.

Ideally for ATTR-CA planar/WB and SPECT images should be performed and evaluated in the clinical context, visual scoring and semiquantitative analysis as each of them present different advantages and disadvantages. Therefore, in accidental diagnosed cases, if SPECT is unavailable, the ATTR-CA diagnosis can be determined by correlating the visual score, with the H/CL and H/R ratios.

CONCLUSIONS

In an ideal situation for diagnosing ATTR-CA, standard protocol should be followed regardless. Therefore, acquired images should be planar/WB followed by SPECT between 2-4 hours. Early planar/WB images, if acquired, present an approximation of the myocardium size and position, but cannot ascertain the presence of ATTR-CA. If SPECT images cannot be acquired, planar images should be enough to make a correct diagnosis, by analyzing them throw visual scoring and semiquanti-

tative analysis (H/CL and H/R).

To conclude, planar/WB vs SPECT, ideally together, if not possible, at least planar/WB for a correct diagnosis of ATTR-CA.

THE PREDICTIVE VALUE OF RED BLOOD CELL DISTRIBUTION WIDTH-COEFFICIENT OF VARIATION IN PREGNANT PATIENTS WITH TREATED THROMBOPHILIA WHO DELIVERED VIA CESAREAN SECTION AT TERM (Abstract): RDW-CV has predictive value in many early-pregnancy-related conditions. Research question: Can RDW-CV be utilized predictively in pregnant patients at term with thrombophilia? **Materials and methods:** We compared RDW-CV values, antepartum and postpartum, according to postpartum uterine involution, maternal features, and fetal outcomes in 79 pregnant patients with treated thrombophilia, who formed the study group, and in another 80 patients of a similar age and parity, who formed the control group. Every patient received a sonogram during the first 1–2 days after the cesarean section, and their uterine evaluation was interpreted using the PUUS (Postpartum Uterine Ultrasonographic Scale). **Results:** Our group of PUUS ≥ 1 pregnant and postpartum patients with treated thrombophilia was the only group with an RDW-CV value over 14. An RDW-CV of 14.5 was the highest value in the Rh-negative group of pregnant patients with treated thrombophilia. An RDW-CV of 14.48 was the highest level in the Rh-negative postpartum patients with treated thrombophilia. (4) **Conclusions**: An RDW-CV of ≥14 might predict uterine hematometra (PUUS ≥ 1). The RDW-CV values were higher in the Rh-negative patients. **Keywords:** RDW-CV, THROMBOPHILIA, PREGNANCY, CESAREAN SECTION, ULTRASONOGRAPHY.

INTRODUCTION

Thrombophilia is a medical condition characterized by an increased tendency to form blood clots (1). Previous studies have shown a relationship between thrombophilia and pregnancy-related issues such as recurrent pregnancy loss (RPL), complications with in vitro fertilization, implanta-

tion failure, and ovarian hyperstimulation syndrome (1, 2).

Previous studies also found that the postoperative RDW and inflammatory biomarkers were significantly higher in transfused cesarean section parturients (3-5), which suggests a significant association between the postoperative inflammatory response and transfusion in obstetric patients.

Febra (6) demonstrated a significant association between an early high RDW and the diagnosis of acute unprovoked deep vein thrombosis. An RDW of ≥14% was found to be an independent predictor of unprovoked venous thromboembolism in adult patients.

The aim of this study is to ascertain whether uterine involution, assessed with the help of Postpartum Uterine Ultrasonographic Scale (PUUS) can be predicted by RDW-CV values.

MATERIALS AND METHODS

This is a secondary analysis of a previously published study (7). In this retrospective study with prospective data collection, we included 159 pregnant patients, comprising 79 pregnant patients with treated thrombophilia in the study group and another 80 patients of a similar age and parity. After gathering the study group, consisting of 80 patients, we added by intent a similar number of patients who were age- and para-matched, and then we removed one thrombophilia patient whose data were incomplete (tab. I). The inclusion criteria were as follows: pregnant patients at term, with known thrombophilia, receiving low-molecular-weight heparin treatment, and who were referred to our hospital for delivery at term by means of a cesarean section between the 1st of October 2017 and the 1st of December 2021. Hospital policy required that patients already diagnosed with thrombophilia be provided a cesarean section at 38 weeks' gestational age, and these patients comprised the study group. All of the patients with thrombophilia already had established diagnoses. Treatment with low-molecular-weight heparin was ongoing. Thrombophilia screening tests were not available at the study hospital; thus, the control group had their blood sent to specialized laboratories for screening, and patients were included following a negative result. The exclusion criteria were as follows: patients with diseases that prohibited heparin therapy (n = 0), patients with insufficient data (n = 1), patients suffering from thrombocytopenia (n = 2), patients with deep vein thrombosis (n = 0), and patients with cerebral thrombosis (n = 0) (7).

TABLE I.

Patient characteristics: mean, median, standard deviation, and quartile 1 and 2 values (7).

Patients	Thrombophilia Patients (n = 79)	Non-Thrombophilia Patients (n = 80)	Significance, p
Age (years)	30 (±5) 30 (27–34)	30 (±5) 30 (27–34)	0.944
Gestation (number)	3 (±1) 3 (2–3)	2 (±1) 2 (1–2)	<0.001
Parity (number)	2 (±1) 2 (1–2)	2 (±1) 2 (1–2)	0.213

There were no thrombophilia mutations identified in the control group. The nonparametric Mann–Whitney test was used for comparisons.

Every patient received a sonogram during the first 1–2 days after cesarean section, and the uterine evaluation was interpreted with the PUUS (Postpartum Uterine Ultrasonographic Scale). This scale (7, 8) counts the quarters of missing uterine vacuum lines, which could be due to the presence of blood or debris as follows:

- In grade 0, the uterine cavity is completely empty.
- In grade 1, there is a small amount of blood or debris occupying less than one-quarter of the vacuum line.
- In grade 2, there is a slightly larger amount of blood or debris occupying less than two-quarters of the vacuum line.
- In grade 3, there is a large amount of blood or debris occupying less than three-quarters of the vacuum line.
- In grade 4, there is a large amount of blood or debris occupying more than three-quarters of the vacuum line (7, 8).

We further referred to this debris as "uterine hematometra". In a previous study (7) on the same group of patients, we presented the demographic, maternal, and fetal outcomes.

The values and characteristics of the patients' blood following analysis were extracted from the hospital's medical records. For this study, the complete blood count values-the first count was obtained antepartum, and the last count was obtained postpartum-were considered. Hospital policy required blood analyses both 24 hours before and after labor.

We performed a blood analysis using MAN-HEMATO laboratory equipment.

We performed a data analysis using *SPSS version 18.0* (PASW Statistics for Windows, Chicago: SPSS Inc., Chicago, IL, USA). We determined the mean and median values, standard deviations, and quartiles. We also used the nonparametric Mann-Whitney U test and Spearman's correlation. We considered $p < 0.05$ to indicate significance (7).

We conducted this study in accordance with the Declaration of Helsinki and approval No. 9/17.09.2017 of the Ethics Committee of "Elena-Doamna" Clinical Hospital of Obstetrics and Gynecology Iasi.

RESULTS

First, we aimed to elucidate whether there was any difference in the involution of the uterine cavity postpartum using the PUUS. Because we had few patients with PUUS grades 1–4, we considered PUUS $\geq$ 1 to indicate any uterine cavity that did not close during the first 48 h postpartum, and we compared these with uterine cavities that did close, designated PUUS = 0, to simplify the comparison.

There was no significant difference between the RDW-CV values in the patients with PUUS = 0 as compared to those with PUUS $\geq$ 1, neither in pregnant patients with treated thrombophilia nor in the non-thrombophilia patients (tab. II). However, the PUUS $\geq$ 1 pregnant and postpartum patients with treated thrombophilia were the only group with RDW-CV $\geq$ 14.

There was a weak negative correlation between RDW-CV and age in the non-thrombophilia pregnant and postpartum patients (tab. III): RDW-CV decreased with increasing age among the non-thrombophilia patients.

TABLE II.

RDW-CV values in treated thrombophilia patients and non-thrombophilia patients, with a closed uterine cavity within 24–48 hrs. (PUUS = 0) or not (PUUS ≥ 1).

The upper line represents the mean values with the standard deviation; the lower line represents the median values with quartiles 1 and 3.

RDW-CV in Pregnant Patients with	PUUS = 0	PUUS ≥ 1	Significance, p
Treated thrombophilia	13.77 ± 1.60 13.51 (12.73; 14.65)	14.06 ± 1.77 14.02 (13.27; 14.26)	0.546
Non-thrombophilia	13.77 ± 1.30 13.47 (12.84; 14.38)	13.43 ± 1.15 13.59 (13.19; 14.23)	0.917
RDW-CV in Postpartum Patients with	**PUUS = 0**	**PUUS ≥ 1**	**Significance, p**
Treated thrombophilia	13.96 ± 1.80 13.53 (12.72; 15.08)	14.04 ± 1.76 13.72 (13.11; 14.59)	0.765
Non-thrombophilia	13.80 ± 1.37 13.26 (12.87; 14.55)	13.60 ± 1.13 13.67 (13.20; 14.40)	0.742

PUUS: Postpartum Uterine Ultrasonographic Scale.

TABLE III.

The correlation coefficients between RDW-CV and patient age.

Pregnant Patients	Correlation Coefficient	Significance, p
Treated thrombophilia	−0.110	0.300
Non-thrombophilia	−0.288	0.009
Postpartum Patients	**Correlation Coefficient**	**Significance, p**
Treated thrombophilia	−0.110	0.330
Non-thrombophilia	−0.350	0.002

There was no correlation between RDW-CV and the number of gestations of the patients. There were no significant differences in the RDW-CV values of the four ABO blood groups. There was no correlation between RDW-CV and the ABO blood group.

There was no significant difference between RDW-CV in the two Rh blood groups (tab. IV). There was no correlation between RDW-CV and the Rh blood groups. However, the Rh-negative pregnant patients with treated thrombophilia had the highest RDW value at 14.5, and postpartum the same group had the highest value, at 14.48.

There was a weak correlation between RDW-CV and BMI in the pregnant and postpartum patients with treated thrombophilia (tab. V), indicating that RDW-CV increased with increasing BMI among the patients with treated thrombophilia.

There was no correlation between the fetal outcomes and RDW-CV values.

TABLE IV.

RDW-CV values in treated thrombophilia patients and non-thrombophilia patients according to the Rh blood factor.

The upper line represents the mean values with standard deviations; the lower line represents the median values with quartiles 1 and 3.

RDW-CV in Pregnant Patients with	Rh-Positive	Rh-Negative	Significance, p
Treated thrombophilia	13.73 ± 1.56 13.58 (12.76; 14.45)	14.50 ± 1.96 14.54 (12.77; 16.17)	0.291
Non-thrombophilia	13.70 ± 1.29 13.48 (12.85; 14.30)	13.90 ± 1.17 13.68 (12.83; 14.84)	0.671
RDW-CV in Postpartum Patients with	**Rh-Positive**	**Rh-Negative**	**Significance, p**

Non-thrombophilia	13.76 ± 1.35 13.47 (12.86; 14.53)	14.01 ± 1.25 13.78 (12.98; 14.81)	0.577

TABLE V.

The correlation coefficients between RDW-CV and maternal features.

Pregnant Patients	Feature	Correlation Coefficient	Significance, p
Treated thrombophilia	Height	−0.094	0.409
	Weight	0.168	0.139
	BMI	0.236	0.037
Non-thrombophilia	Height	0.140	0.215
	Weight	0.117	0.302
	BMI	0.039	0.731
Postpartum Patients	**Feature**	**Correlation Coefficient**	**Significance, p**
Treated thrombophilia	Height	−0.052	0.656
	Weight	0.217	0.061
	BMI	0.279	0.015
Non-thrombophilia	Height	0.108	0.365
	Weight	0.132	0.269
	BMI	0.076	0.525

BMI = body mass index.

DISCUSSION

RDW-CV demonstrates anisocytosis (9). The higher the RDW-CV value, the more serious the anisocytosis. RDW-CV increases in many diseases. A decreased value means that the cells are mostly uniform in size.

Febra (6) demonstrated a significant association between an early high RDW and the diagnosis of acute unprovoked deep vein thrombosis. An RDW of ≥14% was found to be an independent predictor of unprovoked venous thromboembolism in adult patients. Our group of PUUS ≥ 1,

pregnant patients with treated thrombophilia had an average RDW of 14.06 (tab. II) and was the only group with an RDW value over 14. The postpartum group, like the postpartum patients with treated thrombophilia, had an RDW-CV of 14.04 and remained the only group with an RDW-CV over 14, even after delivery. Nevertheless, this group showed no deep vein thrombosis during hospitalization, suggesting that the anticoagulant treatment was necessary and effective.

Here is an important clinical implication: since only the treated thrombophilia patients whose uterine cavities did not involute had an RDW-CV over 14%, they were also at risk of venous thromboembolism. This makes sense. RDW-CV reflects anisocytosis, which generates thrombosis. Thrombosis did not occur due to the anticoagulant treatment, but anisocytosis remained. This means that thrombophilia patients with an RDW-CV over 14% are at risk of having a slower postpartum uterine involution, and they will require extra medical attention.

An RDW-CV of 14.5, the highest value, occurred in the Rh-negative pregnant patients with treated thrombophilia, indicating that a Rh-negative status is a potential predictor of deep vein thrombosis in pregnant patients with thrombophilia. An RDW-CV of 14.48 was the highest value in the postpartum group, occurring specifically in the Rh-negative postpartum patients with treated thrombophilia, and an RDW-CV of 14.01 was the highest value in the Rh-negative non-thrombophilia postpartum patients.

There was a weak negative correlation between RDW-CV and age in the non-thrombophilia pregnant patients; RDW-CV decreased with increasing age among the pregnant patients.

In pregnant women with obesity, RDW is lower, indicating that a larger maternal body size during pregnancy generates more and smaller erythrocytes (10). In our study, RDW-CV increased with increasing BMI among the pregnant patients with treated thrombophilia and was not influenced by BMI in the non-thrombophilia pregnant patients, showing that either the condition or treatment of thrombophilia, associated with a higher BMI, generated anisocytosis.

There was no correlation between fetal outcomes and postpartum RDW-CV values. This is in accordance with a study in Croatia, which demonstrated that asymptomatic carriers of inherited thrombophilic polymorphisms do not have an increased risk of adverse perinatal outcomes (11).

The strength of this work is that, to the best of our knowledge, it is the first to correlate RDW-CV and uterine postpartum involution, and it is also the first to do this in thrombophilia patients. The weakness of this work is that the number of patients was small, so further studies including more patients, and eventually more medical centers, are required in order to confirm these results.

CONCLUSIONS

In treated thrombophilia pregnant patients, an RDW-CV value over 14% might be a predictor of late postpartum uterine involution (PUUS grade ≥ 1).

The RDW-CV values were higher in the Rh-negative patients.

EVALUATING THROMBOTIC RISK IN PATIENTS WITH COLORECTAL AND GASTRIC CANCER (Abstract): We decided to study the computed tomography appearance and staging of gastric and colorectal cancers in relationship with vein thrombosis and pulmonary embolism because these tumors and their thrombotic complications are leading causes of morbidity and mortality in adult patients. **Materials and methods:** We retrospectively searched the databases of "Sf. Spiridon" County Clinical Emergency Hospital, Iasi, and we discovered 102 patients with gastric and colorectal cancer who underwent computed tomography (CT) with a 64 detectors Incisive Philips CT scan between January and December 2022. The study was focused on the CT appearance of the tumor (location, length and thickness, local invasion), lymphadenopathies, metastases, and the correlation between tumor characteristics and the tendency for vein thrombosis. **Results:** We studied 102 patients (77 with colorectal and 25 with gastric cancer), mean age: 68.85±13.13 years, and among them we discovered 19 (18.62%) cases with vein thrombosis. Cancer-associated thrombosis has a weak negative correlations tumor thickness and length, weak positive correlation with tumor extension outside the digestive wall, number of loco-regional lymphadenopathies, and metastases. **Conclusions:** We found a strong association between vein thrombosis and gastric and colorectal malignant tumors, there is a weak correlation with tumor extension outside the digestive wall, the number of loco-regional lymphadenopathies and the presence of metastases, so we cannot confidently predict thrombosis by studying these tumor characteristics. **Keywords:** GASTRIC CANCER, COLORECTAL CANCER, THROMBOSIS.

INTRODUCTION

Malignancy leads to a hypercoagulable state associating vein thrombosis and / or pulmonary embolism (1), cancer patients having a 4 times higher risk of thromboembolism than general population (2, 3). Cancer-associated thrombosis is the second mortality cause, following the mortality by cancer itself, and preceding the mortality determined by various infections (4); mortality is lower in cancer patients without deep vein thrombosis and / or pulmonary embolism and significantly higher in case of those associating thrombosis (5, 6). Gastric cancer and colorectal cancer are leading causes of morbidity and mortality in

adult patients, many authors studied the frequency of associated venous thromboembolism, and created strategies for prophylaxis and treatment (7). Most patients with gastric cancer and colorectal cancer have no obvious clinical symptoms in the early stage, are diagnosed at an advanced stage, when pain, fatigue, and even jaundice can appear, related to lymphadenopathy or liver metastases (8). Thrombosis can be an early symptom of cancer, but the incidence of varies with cancer type, stage, patient characteristics, and anticancer-associated treatment (9, 10). Computed tomography has a high sensitivity for gastric cancer detection (11) and is the gold standard method for evaluating tumor invasion, regional and distant lymphadenopathy, liver and peritoneal metastases (which are associated with poor prognosis) (12, 13, 14). For colorectal cancer, computed tomography is also the standard method for determining disease stage but staging is improved in case of rectal cancer by using MRI which has been documented to be more accurate than CT (15). Current therapeutic agents of digestive tract cancer-associated thrombosis mainly comprise low weight molecular heparins, and eventually inferior vena cava filters, because oral anticoagulants, and vitamin K antagonists are contraindicated (5, 7, 10).

MATERIALS AND METHODS

We retrospectively searched the databases of "Sf. Spiridon" County Clinical Emergency Hospital Iaşi to identify patients who underwent abdominal and pelvic contrast enhanced CT (CECT) for suspicion of gastric and colorectal cancer during 2022 and we discovered 102 patients with imaging suspicion for these malignancies; among them 24 had also suspicion of vein thrombosis or pulmonary embolism (PE) and computed tomography pulmonary angiography (CTPA) was also performed.

Computed tomography was performed with a 64 detectors Incisive Philips CT scan; for those patients with PE suspicion, CTPA was performed, followed by abdominal and pelvic CT examination, for the other patients only abdominal and pelvic CT was done. All patients with suspicion of gastric cancer ingested immediately prior the investigation 500 mL water to distend the stomach and those with colorectal cancer underwent a colonic cleansing preparation followed by a 1500-2000 mL water enema before the procedure.

A noncontrast enhanced scan was performed on the regions of interest. We injected intravenously up to 100 mL of 400 mg I/mL Iomeprol (Iomeron 400 mg/mL) for CTPA and up to 120 mL of 370 I/mL Iomeprol (Iopamiro 370 mg/mL) for abdominal and pelvic CECT, with an automatic injector, with the speed of 3-4 mL/second, followed by 50 mL of saline chaser; we used bolus tracking technique to choose the moment of arterial phase scanning for CTPA: the scan started with a delay of 22-25 seconds when the density in the pulmonary trunk was over 150-180 HU.

For abdominal and pelvic CT scan we measured the CT densities during contrast injection in the descending aorta just above the diaphragm; when the density was over 120 HU, the scanning started with an injection-to-scan delay for the arterial phase 15-20 seconds, for portal venous phase 60-70 seconds, and 4 minutes for delayed phase.

Gastric cancer and colorectal cancer staging are based on the 8th edition of the AJCC TNM classification of malignant tumors (16, 17).

The study was focused on the following

features: CT appearance of the tumor (location, length and thickness, local invasion), lymphadenopathies, metastases, and the correlation between tumor characteristics and the tendency for vein thrombosis and PE.

RESULTS

We studied 102 patients (77 with colorectal and 25 with gastric cancer), and among them there were 64 (62.75%) males and 38 (37.25%) females, with mean age: 68.85±13.13 years, age range: 18 to 93 years, the majority of patients concentrated in the 60-80 age range (57-55.88% patients), with the highest concentration around the age of 70. We encountered only five sincrone or metacrone large bowel tumors and two associations between colonic and gastric cancer.

The study of the tumor length (fig. 1) and thickness in correlation with age group, shows a wide range of tumor dimensions, with an ascending trend from 20 to 80 years, the 60-80 years group having the highest variability in tumor dimensions, with the median being higher than the previous age groups suggesting that older patients might have tumors detected at later stages.

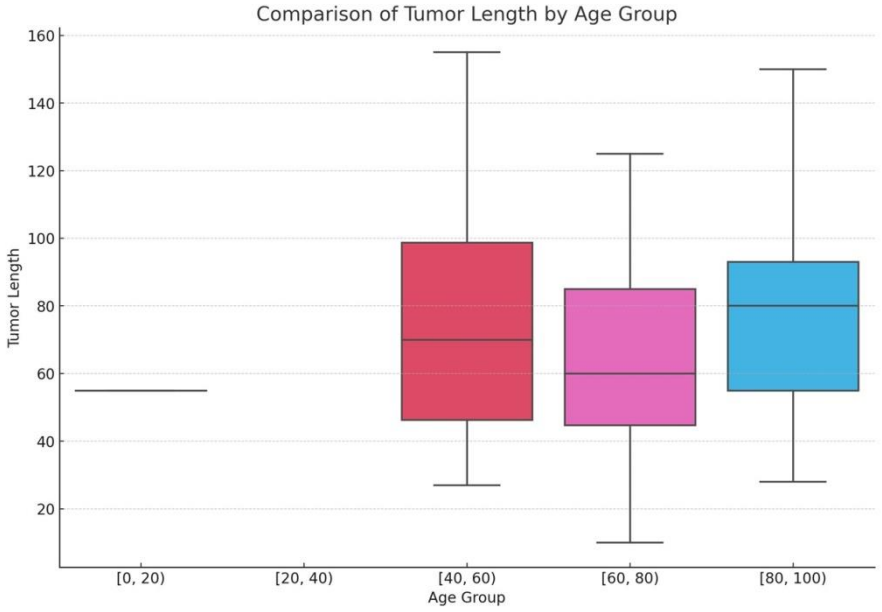

Fig. 1. Relationship between tumor length and age group

We used Pearson correlation coefficient (r) and p-value to measure the strength and direction of the linear relationship between two variables; r ranges from -1 (perfect negative linear relationship) to 1 (perfect positive linear relationship) and p-value is significant between $0.001 \leq$ and < 0.05.

Correlations between tumor characteristics and loco-regional tumor extension

The localization of the tumors influences treatment strategies, so it is important to notice the most frequent locations: in case of the large bowel, rectum and sigmoid have a higher prevalence of tumors (37-48.05%

cases), followed by ascending colon (14-18.18%). Gastric cancer has an equal distribution between antrum: 8 cases (32%), fornix and body (7-28% cases each), other localizations being rarer.

Among all the patients we had studied the highest number of invasive tumors are present in the rectum and sigmoid colon (18-17.64% cases), cecum and ascending colon (10-9.80% cases), and indicating that the lesions with these locations have a higher tendency for local invasion; even if there were only 7 invasive gastric tumors, they represent a significant percentage (6.86% of all lesions and 28% of gastric cancers).

The r values we calculated for tumor thickness reveal that is moderately correlated with both tumor length (0.526) and the extension of the tumor outside the digestive walls (0.325), indicating that as tumors become thicker, they tend to grow larger and invade surrounding tissues more extensively; while there is some relationship between tumor thickness and the number of loco-regional lymphadenopathies, it is relatively weak (0.225), and age appears to have a minor inverse relationship with tumor thickness, but this correlation is also weak (-0.188).

Pearson correlation coefficient and p-values show the significance of tumor thickness correlations with tumor length, extension of the tumor outside the digestive walls, number of loco-regional lymphadenopathies, concluding that they are not likely due to random chance (tab. I).

TABLE I.

Correlations between tumor thickness and other variables

Tumor thickness	Pearson correlation coefficient	p-value	Classification
Tumor length	0.526	<0.001	Highly Significant
Thickness Outside the Digestive Walls	0.325	<0.001	Highly Significant
Number of loco-regional adenopathy	0.225	<0.05	Significant
Age	-0.188	<0.1	Marginally Significant

Tumor length shows a moderate positive correlation with thickness outside the digestive walls (0.470) and a weak positive correlation with locoregional adenopathy number (0.238). Thickness outside the digestive wall shows a moderate positive correlation with locoregional adenopathy number (0.490).

The most frequent metastasis are the liver ones (21-20.58%) (fig. 2), followed by peritoneal and non-regional lymphadenopathies (10-9.80%), pulmonary (8-7.84%), splenic, renal, and bone secondary lesions (1-0.98%). Age distribution of liver metastases ranges from 50 to 89 years, common age group is over 70 years (13-61.90% cases) and the prevalence concerning the gender is in favor of male patients (15-71.42%). The correlation between liver and other metastatic sites is the following:

- with the peritoneal and non-regional lymph node metastases is moderate positive: patients with hepatic metastasis are likely to have peritoneal and non-regional lymph nodes metastasis as well;
- with pulmonary metastasis there is a weak correlation, suggesting a lower likelihood of co-occurrence with liver metastasis;
- splenic, renal, and bone metastasis exhibit a very weak or no correlation with liver metastasis, so they are rarely found together with hepatic metastasis.

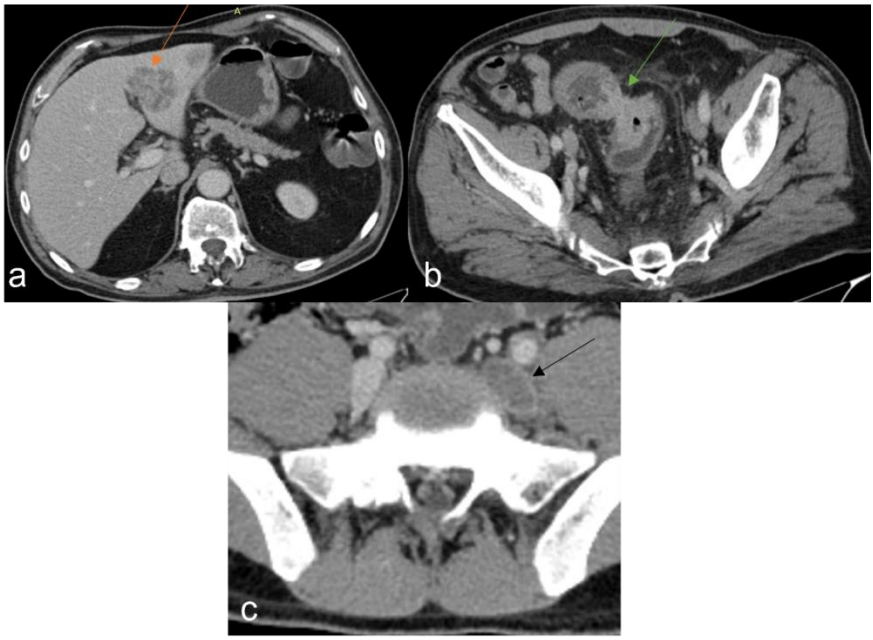

Fig. 2. Abdominal and pelvic CT, portal venous phase: a. liver metastases (orange arrow); b. sigmoid colon cancer (green arrow); c. left common iliac vein thrombosis (black arrow)

Correlations between tumor characteristics and vein thrombosis

Among the patients we had studied we found 19 (18.62%) cases with vein thrombosis associated with pulmonary embolism in 7 (6.86%) cases, most of them (15-78.94%) being males. This study discovered the following correlations between vein thrombosis and tumor characteristics (fig. 3):

- with tumor thickness and length: weak negative correlations; for example, the tendency of vein thrombosis is not increasing with tumor thickness (coefficient is -0.0017), indicating a slight negative relationship with thrombosis, also this relationship is not statistically significant ($p = 0.061$);
- with tumor extension outside the digestive wall: weak positive correlation;
- with number of loco-regional lymphadenopathies: weak positive correlation (0.306), suggesting that higher loco-regional adenopathy numbers are slightly associated with an increased likelihood of thrombosis;
- portal vein thrombosis: weak correlations with tumor thickness (-0.084), tumor length (-0.035), and thickness outside the digestive walls (-0.071), and moderate correlations with other thrombosis types such as iliac vein thrombosis (0.219) and inferior vena cava thrombosis (0.243).

Studying the TNM staging we found only 10 cases of T1-T2 lesions, and most of the patients had locally advanced tumors in 92 (90.19%) cases (T3: 42 cases, T4: 50 cases). The majority of patients (86 cases-84.31%) had lymph node involvement (N1: 52 cases, N2: 22 cases, N3: 12 cases), but distant metastases were present in 37 (36.27%) cases. The correlation of TNM categories and the tendency for vein thrombosis are presented in second table.

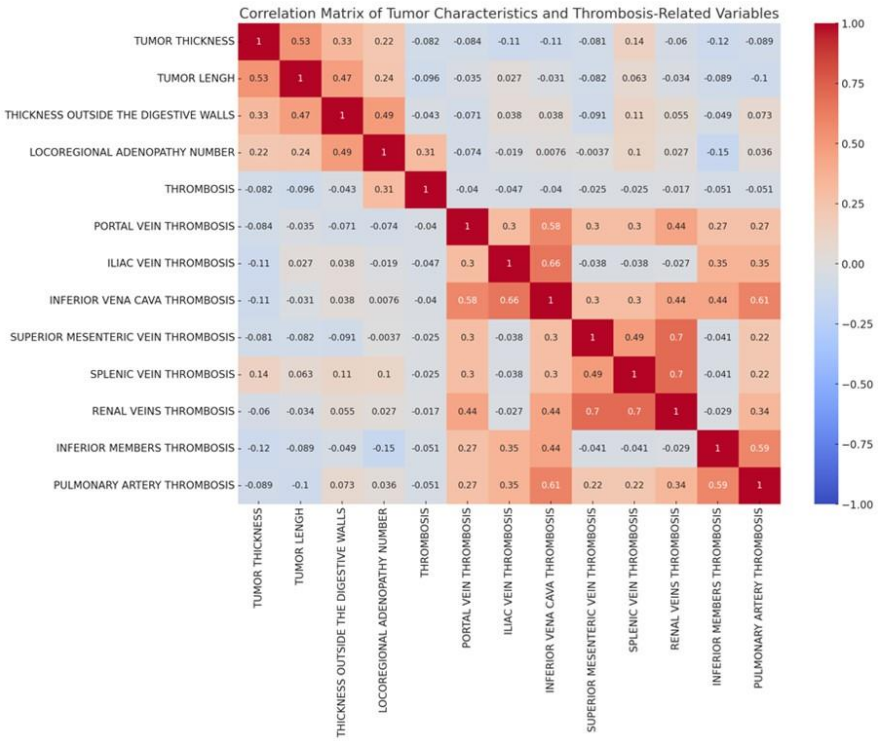

Fig. 3. Correlations between tumor characteristics and thrombosis:
red = positive, blue = negative; the intensity of the color = the strength of the correlation

TABLE II.

Correlation between TNM categories and the tendency for thrombosis

Thrombosis	Pearson correlation coefficient	p-value	Classification
T	-0.327	0.040	Significant
N	0.306	p < 0.001	Highly Significant
M	0.178	0.040	Significant

Tumoral local invasion (T) has the coefficient -0.327, indicating a negative relationship with thrombosis, which is statistically significant (p = 0.040). However, there is a weak correlation between the number of loco-regional lymphadenopathies and thrombosis (r= 0.306), for each additional locoregional adenopathy, the thrombosis score increases; this relationship is statistically significant (p < 0.001), suggesting that patients with more loco-regional lymphadenopathies might have a higher likelihood of developing thrombosis. The presence of metastases has a weak positive(r=0.178), statistically significant (p = 0.040) correlation with vein thrombosis.

DISCUSSION

We studied 102 patients and among them only 25 had gastric cancer, determining an inaccurate statistic for this particular group, so we studied the correlations between tumor characteristics and the rela-

tionship with cancer-associated thrombosis for the whole group of patients.

Gastric and colorectal cancers were frequent (62.75%) in case of male patients, and liver metastases have a higher prevalence in males (71.42%), suggesting the need for gender-specific strategies in early detection and follow-up for this demographic.

The majority of patients are concentrated in the 60-80 age range (55.88% patients), and liver metastases are frequent in case of patients over 70 years old (61.90%) so the surveillance for gastric and colorectal cancers has to be extended also for these age groups.

Although the association between gastric tumors (including neuroendocrine ones) and breast cancer (mainly lobular type) is cited in the literature, we found this association only in 1 case, without any correlation with vein thrombosis (18, 19, 20). Among the patients we had studied we found a significant number (19-18.62%) of vein thrombosis, most of them (15-78.94%) being males; this tendency suggests that the appearance of thrombosis in case of a male subject to ring a bell for the presence of a malignant tumor.

The correlations between thrombosis and tumor thickness and length are weak negative correlations; tumor extension outside the digestive wall has a weak positive correlation with thrombosis.

Tumoral local invasion in other organs has a statistically significant, negative relationship with thrombosis, but between the number of loco-regional lymphadenopathies and the presence of metastases there is a weak positive correlation with vein thrombosis.

For further studies we think about correlating malignant gastric, colonic and pancreatic lesions with vein thrombosis, heart conditions and COVID-19 infection, using artificial intelligence programs (21, 22).

CONCLUSIONS

Most of the patients with metastatic gastric and colorectal cancers from our study were old males, who had also cancer associated thrombosis, so the surveillance for these malignancies has to be focused on them and also extended for older age groups.

Even if we found a strong association between vein thrombosis and gastric and colorectal malignant tumors, there is a weak correlation with tumor extension outside the digestive wall, the number of loco-regional lymphadenopathies and the presence of metastases, so we cannot confidently predict thrombosis by studying these tumor characteristics.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

SELF-EVALUATION OF NURSING STUDENTS REGARDING THEIR COMMUNICATION SKILLS (Abstract): **The objective of the study** was to evaluate the confidence of nursing students regarding their communication skills and how prepared they felt working with different kinds of patients. **Materials and methods**: 160 students enrolled in nursing studies from all years of study were included in the research. An online questionnaire was constructed for the present study to gather sociodemographic and academic data. Additionally, self-rated items were created to collect information about students' confidence in their communication skills. Two instruments were used to evaluate their learning communication skills and interpersonal communication competence: *Interpersonal Communication Competence Scale* and *Communication Skills Attitude Scale*. **Results**: Nursing students who scored high on the *Communication Skills Attitude Scale* demonstrated greater engagement in social interactions and exhibited supportiveness and promptness in their relationships with others. Only 7.5% of participants reported receiving additional training in communication skills. Freshman students perceived communication with elderly patients more challenging compared to students in advanced years. **Conclusions**: Theoretical and practical stages of continuing education after graduating from nursing schools are essential requirements for nurses. This ensures that they can effectively apply their knowledge and skills across various healthcare settings and cater to different categories of patients. Direct feedback during practical stages and moral support from academic teachers and clinical trainers help students to feel more confident about their communication skills. **Keywords:** NURSING STUDENTS, COMMUNICATION SKILLS, ACADEMIC TRAINING, EMPATHY.

INTRODUCTION

The nursing profession is one of the most challenging professions because it involves working with people in a vulnerable situation, both physically and mentally. This situation has a negative impact on the personal and professional life, but also on the family and social life of the patient. Therefore, nurses need to develop effective communication skills with patients and undergo thorough theoretical and practical training during their academic years. This preparation allows them to work competently with different categories of patients, including pediatric, elderly, chronic, palliative, and those with disabilities. Poor

nurse-patient communication can lead to lower satisfaction, reduced adherence to treatment recommendations, and poorer health outcomes (1).

Nursing students must focus on curricular and extracurricular training to develop their skills in therapeutic communication (TC). TC is defined as the process of using verbal and nonverbal communication to connect with patients (2). In the medical context, nurse-patient communication represents not only an exchange of objective information, but also addresses physiological, psychological, environmental and spiritual care. It also includes beliefs about recovery, life perspectives, relevant concerns about disease and personal needs. (3) Students must be encouraged to develop their desire for lifelong learning and acquisition of communication skills, in relationship with their permanent needs and job-related context. In academic nursing training, scholars recommend incorporating video-training and practical sessions based on scenarios that allow students to analyse and practice their skills. Fioravanti, *et al.* (4) and Kaplonyi *et al.* (5) identified that realistic situations provided good opportunities to improve the competencies of nursing students through human interaction and immediate feedback, while Moscaritolo (6) recommended peer instruction and mentoring as effective methods for improving nursing students' skills. Cannity *et al.* (7) identified three directions for efficient training: responding empathically to patients; discussing death, dying, and end-of-life goals of care; and responding to challenging family interactions. In the light of recent trends in providing medical care, many researchers also recommend training nurses in communication skills applicable to intercultural environments. This recommendation is due to the increasing rate of migration of nurses for work and patients seeking better care abroad. For example, Didgson, *et al.* (8) identified the necessity to enhance nurses' cultural competency in the context of globalization, while Demelius (9) mentioned the importance of providing opportunities for nurses to experience different cultures and interact with people from different cultural backgrounds. In their study, Szpak and Kameg (10) identified that numerous nursing students reported anxiety or lack of confidence in their ability to communicate with patients as barriers to effective communication. These barriers included reluctance to engage with patients or families, difficulty initiating or maintaining conversations, feeling underappreciated and anxious about engaging in complex discussions such as those involving death and dying. Additionally, concerns about their professional performance was cited as a source of job-related stress. The present study aimed at the self-evaluation of nursing students enrolled in nursing studies about their confidence when communicating with patients during their practical stages in hospitals.

MATERIALS AND METHODS

Participants

The study was conducted from October to December 2024 among nursing students. The participants were students enrolled in all years of study at the "Grigore T. Popa" University of Medicine and Pharmacy of Iasi / Faculty of Medicine, the participants were informed about the purpose of the study and the confidentiality of data, and about the fact that they could withdraw from the study whenever they wanted, without consequences. No incentives were given to participants. The instrument was

distributed to approximately 430 students. Inclusion criteria comprised students enrolled in Nursing from years of study 1-4. Exclusion criteria: questionnaires filled in after the deadline. Finally, a total of 160 participants were included in the present study, representing 37.21% of the targeted participants.

Study Instruments

The questionnaire was constructed using Google Forms and consisted of three sections:

The first part of the questionnaire collected information about socio-demographic and academic data such as age, marital status, gender, background, year of study, and the employment status.

The second part of the questionnaire collected self-reported data regarding students' opinions on their satisfaction with the communication skills developed during their academic years. It assessed how comfortable they felt when communicating with patients during internships, their perception of the importance of communication skills in their practice, and whether they had attended extracurricular courses focused on developing communication skills. (e.g, *How comfortable do you feel when communicating with patients during your practical stages? Do you consider that communication skills are important for your profession? How difficult do you think the communication is when communicating with patients, during your practical stages as a student? How difficult do you think communication is when working with palliative, paediatric, geriatric, chronically ill patients etc.* Further items collected data about students' experiences and feelings when communicating with family members. Responses were provided using *yes/no* options, or rated such as *very difficult/difficult/not very difficult/not at all difficult*.

The third part of the questionnaire aimed to identify learning communication skills and interpersonal communication competence. To evaluate students' attitudes towards learning communication skills during medical courses, *The Communication Skills Attitude Scale* (CSAS) consists of 26 items, 13 of which are written in the form of positive statements and 13 negative statements regarding communication skills learning. This instrument was developed by Ress *et al.* in 2002 (11). Each item is accompanied by a 5-point Likert scale, ranging from 1 (strongly disagree) to 5 (strongly agree). *The Interpersonal Communication Competence Scale,* developed by Rubbin in 1994 assesses the ten dimensions of interpersonal communication competence (self-disclosure, empathy, social relaxation, assertiveness, altruism, interaction management, expressiveness, support, promptness, and control of the environment) and establishes the quality of the communication process. (12), This scale is composed of 23 items with answers given according to a five-point Likert-type scale (from 1 = *never* to 5 = *very often*). The alpha-Cronbach score for the "Communication Skills Attitude Scale was 0.71 and 0.76 for "Interpersonal Communication Competence Scale", indicating good reliability.

Statistical Analysis

All analyses for the present study were performed using *IBM Statistical Package for Social Sciences (SPSS) Statistics (SPSS Inc, Chicago, IL, USA).* For descriptive data, such socio-demographic and academic information, means and standard deviations (SD) were calculated. The Spearman correlation was used to test the relationship

between variables with a $p < 0.05$ considered statistically significant.

RESULTS

Socio-Demographic and Academic Data

Students from all years of study responded to the questionnaire. The data analysis showed that the majority of students were female from rural area, having no prior experience as nurses and being into a relationship (tab. I).

TABLE I.

Sociodemographic characteristics

Sociodemographic data	n (%), M ± SD
Sex	
Male	11 (6.9)
Female	149 (93.1)
Age	21.16 ± 2.64
Area of origin	
Urban	62 (38.8)
Rural	98 (61.3)
Educational level	
1st year	39 (24.4)
2nd year	32 (20.0)
3rd year	28 (17.5)
4th year	61 (38.1)
Experience as nurse (employed)	3 (1.9)
Marital status	
single	74 (46.3)
in a relationship	86 (53.8)

Self-evaluation of communication skills

Students were asked about their comfort level when communicating with patients during their practical stages. Findings showed that 19 % of the participants felt very comfortable (N = 31), 61.9% declared that they felt comfortable (N = 99), 18.1% felt a little comfortable (N = 29), and only 0.6% felt not comfortable at all (N = 1). The survey revealed that all participants (100%, N = 160) considered communication skills as being an important skill for practicing the nursing profession. Only 7.5% of the participants reported additional training in communication skills. A strong majority of participants declared that empathy was always necessary for nursing (86.3%). A total of 21.9% of the participants (N = 35) sustained that they felt well-prepared to communicate with patients, while 50.6% (N = 81) felt well prepared. When asked about their ability to communicate through non-verbal language (such as gestures, facial expressions, or tone of voice), 7.5% of the participants (N = 12) rated their ability as excellent, and 81.3% (N = 130) rated it as very good. The analysis of data indicated that students found the communication skills training received during university to be moderately to significantly beneficial (M = 3.43), suggesting that most of the nursing students considered that their education played a meaningful role in the development of their communication skills. A total of 62.5% (N = 100) of students reported that the nurses they met during their internships served as role models in terms of communication skills (tab. II).

The questionnaire assessed students' perception of their ability to communicate with patients with chronic illness or other categories such as pediatric or geriatric ones. The results indicate significant differences between years of study in terms of perceived difficulty in communicating with elderly patients ($F(3,156) = 8.073$, $p = 0.000$). Thus, first-year students perceived communication with elderly patients more challenging compared to students in advanced years (MY1 = 1.79, MY4 = 1.40). Similar differences were identified in communication with children: ($F(3,156) = 5.968$, $p = 0.001$), with first-year students perceiving greater challeng-

es than their senior peers (MY1 = 1.41, MY4 = 1.13). Regarding palliative care patients (p = 0.108), no significant differences were found among the four years of study. The perception of difficulty remained consistent regardless of the year of study (F (3,156) = 2.057, p = 0.108). Additionally, no significant differences were found between years of study regarding the perceived difficulty of communication with patients with disabilities (F (3,156) = 1.046, p = 0.374).

TABLE II.
Profile of the nursing student

ITEMS	n (%) M ± SD
How comfortable do you generally feel when communicating with patients during your internships?	
• Very comfortable	31 (19.4)
• Comfortable	99 (61.9)
• A little comfortable	29 (18.1)
• Not comfortable at all	1 (0.6)
Do you think communication skills are important in nursing practice?	
• Yes	160 (100)
Have you taken any extracurricular training to develop your communication skills?	
• Yes	12 (7.5)
How necessary is empathy in the process of communicating with patients?	
• It is always necessary	138 (86.3)
• It is necessary in certain situations	22 (13.7)
• It is not necessary	0 (0)
How well prepared do you feel in terms of communication skills?	
• I feel quite prepared	35 (21.9)
• I feel well prepared	81 (50.6)
• I don't feel sufficiently prepared	44 (27.5)
• I don't feel prepared at all	0 (0)
As a nursing student, how difficult has it been for you to communicate with patients?	
• Very difficult	0 (0)
• Difficult	29 (18.1)
• A little difficult	107 (66.9)
• Not difficult	24 (15)
How do you manage to communicate through non-verbal language (gestures/ facial expressions/ tone of voice) with patients?	
• Excellent	12 (7.5)
• Good	130 (81.3)
• Not at all	18 (11.3)

ITEMS	n (%) M ± SD
Do you feel understood when you are having a conversation with the patient?	
• Yes	151 (94.4)
How difficult is it for you to remain calm and empathetic when the patient is stressed and agitated?	
• Very hard	3 (1.9)
• Heavy	48 (30)
• Easy	98 (61.3)
• Very easy	11 (6.9)
Do you consider that the attitudes of professional nurses are always a model to be followed?	
• Yes	100 (62.5)
Do you find it difficult communicating with multidisciplinary team?	
• Yes	45 (28.1)
On a scale of 1 to 5, how much do you think the information you received during academic years helped you develop your communication skills?	
• 1	4 (2.5)
• 2	22 (13.8)
• 3	63 (39.4)
• 4	43 (26.9)
• 5	28 (17.5)

As some results indicated significant differences between groups. The findings showed that freshman students perceived communication with elderly patients as more difficult than second-year students ($p = 0.002$, [0.13, 0.71]). First-year students significantly perceived communication with elderly patients as more challenging compared to second-year students. Additionally, first-year students significantly perceived communication with elderly patients as more difficult compared to fourth-year students ($p = 0.000$, [0.20, 0.67]). There were no significant differences regarding the perceived difficulty of communication between second-year and third-year students, or between second year and fourth-year students.

The study also explored the level of comfort nursing students experienced when communicating with patients during their practical stages. Students in Y4 reported the highest level of comfort in communicating with patients ($M = 2.02$), followed by students in Y2 ($M = 1.97$). Similar findings were identified for students from Y3 ($M = 1.82$) and Y1 ($M = 1.87$). To explore the relationships between variables regarding the CSAS scale and subsequent dimensions of ICCS, Pearson correlation analysis

was conducted. The results highlighted several significant associations between the variables included in the study. Firstly, the overall CSAS score showed significant positive correlations with self-disclosure ($r = 0.174$, $p = 0.028$), interactions ($r = 0.207$, $p = 0.009$), supportiveness ($r = 0.211$, $p = 0.007$) and promptness ($r = 0.290$, $p<0.001$). These results suggest that nursing students with a high CSAS scale score tended to be more involved in social interactions and showed supportiveness and promptness in their relationships with others. Regarding self-disclosure, it showed significant and positive correlations with relaxation ($r = 0.368$, $p < 0.001$), assertiveness ($r = 0.439$, $p < 0.001$), and expressiveness ($r = 0.424$, $p < 0.001$). These correlations indicate that nursing students who self-disclose were more relaxed, assertive, and expressive in social interactions. Relaxation was also positively associated with assertiveness ($r = 0.494$, $p < 0.001$), supportiveness ($r = 0.337$, $p < 0.001$), and promptness ($r = 0.497$, $p < 0.001$). This relationship emphasizes that nursing students who were relaxed in social contexts tended to be assertive, supportive, and prompt in their responses. A strong correlation was identified between promiscuity and control ($r = 0.513$, $p < 0.001$), suggesting that individuals exhibiting promiscuous behavior tended to have high control over their actions. Furthermore, promptness showed a positive correlation with supportiveness ($r = 0.464$, $p < 0.001$), underlining a link between promptness and supportive attitudes in social interactions. Conversely, variables such as alter centrism and empathy had weak or insignificant correlations with most other variables, suggesting that they were not closely related to the constructs assessed in this study.

DISCUSSION

Our study proved that a significant majority of nursing students (94%) felt well prepared regarding their communication skills, although a small number of students (7%) sustained that they participated to extracurricular training in order to increase their abilities. Increased confidence over the academic years is related to the adequate topics, and their practical stages supervised by their teachers in clinics or hospitals, where nursing students can directly experience professional relationships with patients and family members. Many respondents mentioned that they easily succeeded in remaining calm when facing a conversation with an aggressive or nervous patient. All surveyed students agreed that empathy was an important skill in nursing practice.

Our study demonstrated that nursing students feel comfortable about their verbal abilities but less confident in their non-verbal skills. Nearly 7% of students sustained that they felt they use non-verbal language appropriately. These results proved that students are more focused on verbal communication, which is easier to control, over non-verbal communication, such as body language and intonation. The analysis of results revealed different perspectives on working with pediatric, geriatric, palliative, or patients with disabilities.

These findings suggest that university curricula should be more focused on training students to work with these patient groups. Our results are congruent to those identified in the scientific literature, indicating a requirement for a good theoretical and practical training of students regarding the nurse-patient relationship based on communication skills.

Ahmady *et al.* (2018) emphasised that direct supervision is essential during their

practical stages, making the presence and regular supervision provided by a clinical instructor key factors in facilitating a positive learning experience. Some other studies identified that practical stages decrease students' levels of fear, lack of confidence, and fear of mistake, suggesting increased exposure to practical situations results in decreased stress in nurse-patient communication (13).

Baraz *et al.* (2015) (14) and Panda *et al.* (2021) found that support from clinical staff and teachers supervising practical stages who provide support, supervision and guidance were described as essential and motivating factors in the learning process, with a positive reinforcement for nursing students. The study highlighted the relationships between self-rated ability, satisfaction, and actual performance (15).

Limitations of the study: the first limitation of the research is due to its small number of male subjects. This situation is a common one, considering that there are fewer males enrolled in nursing studies and also working in nursing field, making a comparative analysis based on sex unfeasible. Studies have attempted to identify differences between male and female nurses. For example, Buthelezi *et al.* (2015) showed that male students described themselves as being vulnerable due to cultural perspectives and societal expectations since nursing is viewed as a female-dominated profession in health-care area. Another limitation of the study is related to the fact that the research was conducted in a single center, which means the results cannot be generalized (16).

CONCLUSIONS

Effective communication between patients and healthcare providers is essential for patient care and recovery. Therefore, nursing students must be very well prepared to develop meaningful and adequate relationships with both patients and their families. Communication skills are developed throughout the academic year through theoretical and practical stages. However, continuing education remains a mandatory requirement for nurses to better adapt their knowledge and practical skills to meet the demands of the health organizations and the category of patients they work with. The professional and moral support from academic teachers and clinical trainers empower nursing students to feel more confident about their communication skills.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest, and they received no specific funding regarding this scientific research.

A FINITE ELEMENT ANALYSIS OF MINI-IMPLANT EFFECTS ON THE PERIODONTIUM: FROM BIOMECHANICAL SIMULATION TO ORAL HEALTH AND MENTAL WELLBEING (Abstract): Mini implants are widely used as temporary anchorage devices (TADs) in orthodontics, providing stable and minimally invasive anchorage. However, excessive or misdirected stresses at the bone-implant interface may compromise periodontal integrity and long-term success. To assess stress distribution and bone deformation around orthodontic mini implants under varying insertion angles and load magnitudes using finite element analysis (FEA), and to explore their clinical and wellbeing implications. **Materials and methods:** A 3D FEA model was developed in SolidWorks, based on CBCT data and manufacturer specifications for a titanium mini implant (8×1.7 mm). The bone model consisted of 2 mm cortical and 8 mm trabecular bone layers. Simulations were performed for insertion angles of 30°, 45°, 60°, and 90° under para-axial forces of 1 N and 5 N. Stress and deformation were evaluated using the von Mises criterion. **Results:** The highest stress values were recorded at the implant-cortical bone interface, particularly at 90° insertion, and increased with load magnitude. Stress rose from 27 MPa at 1 N to 266 MPa at 5 N, while bone deformation ranged from a few to several tens of micrometers. Insertion geometry and loading intensity significantly influence the biomechanical behavior of peri-implant bone. Moderate insertion angles (45-60°) ensured a more balanced stress distribution and greater stability. **Conclusions:** Finite element modelling supports personalized, safe, and psychologically comfortable orthodontic treatments, linking biomechanical precision with oral and mental wellbeing. **Keywords:** FINITE ELEMENT ANALYSIS, MINI-IMPLANTS, STRESS DISTRIBUTION, CORTICAL BONE, PERIODONTAL BIOMECHANICS, INSERTION ANGLE, ORAL AND MENTAL WELLBEING.

INTRODUCTION

Mini implants, also known as temporary anchorage devices (TADs), have revolutionized modern orthodontic and periodontal therapy by providing stable, minimally invasive, and cost-effective anchorage for tooth movement and skeletal correction. Their clinical success relies not only on the mechanical design of the implant but also on the complex biomechanical interactions with the surrounding periodontal tissues, including the cortical and trabecular bone, periodontal ligament, and gingival interface (1-4).

Despite their widespread use, the pre-

cise distribution of stress and strain within the peri-implant region remains a critical determinant of biological response and long-term stability. Inappropriate insertion angles or excessive loading may cause microdamage, localized bone resorption, or even implant failure. Conversely, controlled stress levels within physiological limits can stimulate bone remodeling and strengthen osseointegration (5-7).

Finite Element Analysis (FEA) has emerged as a powerful computational method for simulating these interactions in a non-invasive and highly reproducible manner. By combining imaging data (such as CBCT) with accurate material modeling, FEA enables the visualization and quantification of stress patterns within the implant-bone-periodontium complex. This allows clinicians to anticipate biological outcomes under various clinical conditions before treatment is initiated (8-11).

However, current literature has often emphasized mechanical optimization alone, overlooking the broader implications for oral and mental wellbeing. The stability of anchorage systems has direct effects on treatment duration, procedural discomfort, and aesthetic outcomes - all of which influence patient confidence, adherence, and emotional state during orthodontic therapy (12-14). The integration of biomechanical predictability with patient-centered psychological comfort thus represents a new paradigm in contemporary dental care.

Accordingly, the present study aims to perform a finite element analysis of stress distribution and bone deformation around orthodontic mini-implants under different insertion angles and loading conditions. Beyond quantifying mechanical performance, the study seeks to link these biomechanical outcomes with their potential clinical and psychosocial significance, providing a holistic view of mini-implant therapy as a bridge between functional precision and overall wellbeing.

MATERIAL AND METHODS

In this study, a finite element model was developed to determine the stress distribution at the interface between the bone and the orthodontic mini-implant, depending on the insertion angle and the applied force.

The analytical model was generated using imaging data (CBCT) and the characteristics of the mini-implant (8 × 1.7 mm) as specified by the manufacturer. A CBCT scan of the mini-implant inserted into a mandibular mould was performed to accurately observe and reproduce the contact established between the two structures.

For the construction of the analytical model, it was also necessary to determine the characteristics of the mini-implant, namely its dimensions and geometry (morphology). The following algorithm was applied:

I. Determination of the Thread Geometry

Determination of the length of segment (CD), expressed in pixels:

$$CD = \sqrt{(710 - 650)^2 + (565 - 395)^2} = 180 \text{ px}$$

Given that CD = 1.7 mm, we define the ratio:

$$\alpha = 180/1.7 = 106 \text{ px/mm}$$

Verification of the accuracy of the calculated ratio:

$$OB = \sqrt{(1333 - 680)^2 + (730 - 480)^2} = 700 \text{ px}$$

$$700/180 = 3.(8)$$

$$8/1.7 = 4.7$$

Since the ratios are not equal, another possible reference point was sought to

define the 8 mm length (fig. 1)

$$EB = \sqrt{(1333 - 565)^2 + (730 - 395)^2} = 840 \text{ px}$$

$$840/180 = 4.6 \approx 4.7 = 8/1.7$$

In this context, the ratio is corrected to α = 840 / 8 = 105 px/mm.

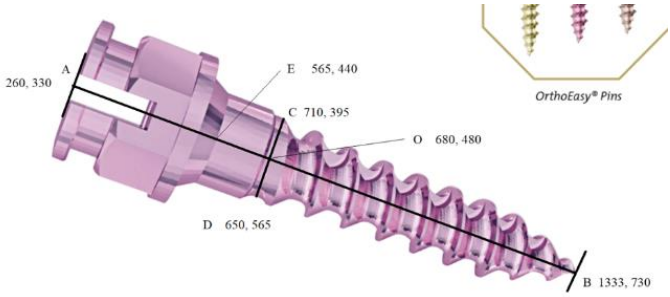

Fig. 1. Determination of the thread geometry using another reference point

II. Approximation of the Screw Geometry

The coordinates of the points are: A(915, 660), B(980, 680), C(980, 655), D(950, 649).Thus, the quadrilateral shown in the image has the following dimensions: AB = 68 px = 0.65 mm, BC = 25 px = 0.24 mm, CD = 30.59 px = 0.29 mm, DA = 46.32 px = 0.44 mm. Determination of the unthreaded segment length: OE = 121.76 px = 1.15 mm s (fig 2).

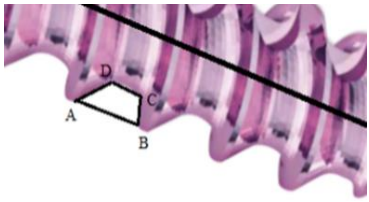

Fig 2. Approximation of the screw geometry

Once the dimensions and morphology of the mini-implant were calculated and analyzed, the 3D model could be created. Using the obtained data, the parameters were transferred into the SolidWorks software, where the analysis proposed in this study was performed using the Finite Element Method (FEM).

In this study, the bone sample was modeled as a cylinder (fig. 3) with a diameter of 10 mm and a height of 10 mm, of which 2 mm represented the cortical bone and the remaining 8 mm corresponded to the trabecular portion. For this geometric body representing the bone, the following material properties were assigned: Young's modulus of 1.5×10^{10} N/mm² (MPa) for the cortical layer and 1.5×10^{9} N/mm² (MPa) for the trabecular component, both with a Poisson's ratio of 0.3.

For the mini-implant, material properties corresponding to titanium were applied, with a Young's modulus of 1.05×10^{5} N/mm² (MPa) and a Poisson's ratio of 0.37. The materials were considered homogeneous, linearly elastic, and isotropic. Subsequently, the two bodies were brought into contact, thereby defining the interface between the mini-implant and the bone.

A total of 16 geometric models were developed according to the objectives of this study, each incorporating the proposed

variable specifically, the insertion angle of the mini-implant (90°, 60°, 45°, and 30°) and the para-axial force applied to it (1 N and 5 N). The stress generated by each applied force on both the mini-implant and the surrounding bone was evaluated, and the results were expressed according to the von Mises stress criterion.

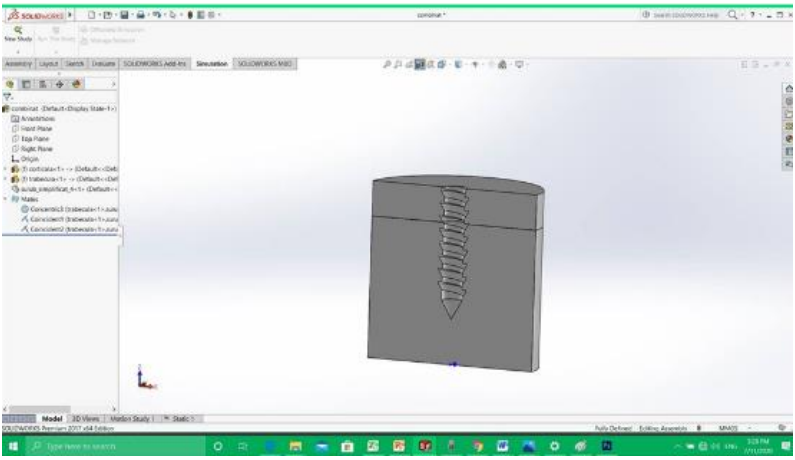

Fig. 3. Raw bone block (section view)

RESULTS

The stress evaluated for the mini-implant with constant dimensions of 8 × 1.7 mm, under different insertion angles (30°, 45°, 60°, and 90°) and applied forces (1 N and 5 N), increased proportionally with both the angle and the magnitude of the applied force. A similar trend was also observed for the stress distributed within the bone.

TABLE I.

Results of the static analysis under a 1 N load

Force value	Inclination relative to the screw axis	Inclination with respect to the screw axis	Maximum bone stress
1N	90 deg	27MPa	13MPa
	60 deg	24MPa	12MPa
	45 deg	18MPa	10MPa
	30 deg	10MPa	6MPa

TABLE II -

Results of the static analysis under a 5 N load

Force value	Inclination relative to the screw axis	Inclination with respect to the screw axis	Maximum bone stress
5N	90 deg	266MPa	70MPa
	60 deg	200MPa	55MPa
	45 deg	145MPa	40MPa
	30 deg	78MPa	23MPa

The maximum stress values on the mini-implant and on the bone were observed, for each applied force, at an insertion angle of 90°. The area subjected to the highest stress was located at the interface between the mini-implant (screw) and the cortical bone. This region exhibited the greatest concentration of stress, which was distributed across both the implant and the bone in all simulations.

The stress gradually decreased within the trabecular bone, where the lowest values were recorded. The bone underwent deformation in the micrometre range under a 1 N load, while at a 5 N load, the deformation increased, reaching values in the tens of micrometres.

DISCUSSION

The current finite element analysis (FEA) offers a detailed exploration of the biomechanical interactions between orthodontic mini-implants and the periodontal support structures. The simulation revealed that both insertion angle and applied load significantly influence the magnitude and distribution of stress at the implant-bone interface. The highest von Mises stress values occurred at 90° insertion, increasing proportionally with force intensity (1N-5N). These results are consistent with previous studies indicating that axial loading amplifies stress transfer to the cortical bone and periodontal ligament, which are the primary structures responsible for implant anchorage and biological adaptation (1, 5, 8, 11, 15).

From a periodontal perspective, the findings highlight the delicate biomechanical balance required to preserve tissue integrity. The cortical layer, with its higher elastic modulus, absorbed the greatest load, while stress values decreased progressively toward the trabecular bone. This gradient is critical for maintaining physiological bone remodeling and preventing microdamage or localized resorption. Excessive compressive stress near the cortical interface can impair microcirculation, limit osteoblastic activity, and initiate inflammatory responses, potentially compromising periodontal health and long-term mini-implant stability (6-10).

In contrast, moderate insertion angles (45°- 60°) produced a more uniform stress distribution, reducing localized peaks within the cortical bone and promoting more favorable load sharing across the periodontium.

This supports the clinical rationale that proper angulation minimizes mechanical trauma to the alveolar crest and reduces the risk of microcracks or cortical perforation - factors that have been correlated with implant loosening or failure in vivo (15-17).

At the tissue level, bone deformation ranged from a few micrometers at 1 N to several tens of micrometers at 5 N, remaining within the physiological tolerance of the periodontal ligament (PDL) and alveolar bone. However, repeated loading, particularly at high forces, may induce micro strain accumulation and activate bone remodeling pathways through mechanic transduction mechanisms. Studies have shown that controlled stress within this range stimulates adaptive bone remodeling, while excessive mechanical input may trigger osteoclastic resorption and connective tissue damage (16-18).

Beyond the mechanical domain, this study aligns with the emerging concept of oral and mental wellbeing in modern orthodontics. The predictable stability of mini-implants contributes to functional efficiency, shorter treatment duration, and reduced anxiety, factors that significantly impact patient satisfaction and psychological comfort. Clinical research has shown that predictable biomechanical control and minimally invasive procedures improve the patient's emotional perception of therapy and enhance treatment adherence (12-14, 19-21). The integration of biomechanical precision with psychological safety thus represents a paradigm shift toward holistic orthodontic care, where success is measured not only by mechanical outcomes but also by quality of life and emotional balance (21).

While the FEA method offers valuable predictive insights, certain limitations must be acknowledged. The model assumes homogeneous, isotropic, and linearly elastic materials, which differ from the anisotropic and viscoelastic behavior of real biological tissues. Additionally, static loading cannot fully replicate the complex dynamic forces of mastication and orthodontic movement. Future research should incorporate patient-specific anatomical models, nonlinear material properties, and in vivo validation to strengthen the translational potential of simulation data (8, 10, 22-24).

In summary, the present study bridges the gap between biomechanical simulation and clinical reality, demonstrating that optimal stress management at the mini-implant-periodontium interface supports both tissue health and patient psychological wellbeing. Such an integrated perspective underscores the future direction of orthodontic innovation: the alignment of engineering precision with human-centered care.

Nevertheless, the present study has limitations inherent to computational simulations. The materials were considered homogeneous, isotropic, and linearly elastic, whereas real biological tissues exhibit anisotropy and viscoelasticity. Moreover, the static loading conditions do not fully replicate the dynamic forces present in vivo. Future research should combine patient-specific 3D imaging, nonlinear material models, and longitudinal clinical validation to establish more precise correlations between simulated stress values and biological outcomes.

CONCLUSIONS

The present finite element analysis demonstrated that both insertion angle and applied load play a crucial role in determin-

ing stress distribution at the mini-implant-bone interface. The highest von Mises stress values were observed at a 90° insertion angle and increased proportionally with load intensity, localizing predominantly in the cortical bone. These findings confirm the cortical layer's key role in load transfer and underline the importance of selecting optimal angulation to minimize concentration zones and prevent microdamage.

From a mechanical standpoint, moderate insertion angles (45°-60°) produced more favorable stress distributions and may contribute to enhanced primary stability, particularly in regions with reduced cortical thickness.

Although the observed bone deformation remained within the physiological range, sustained or excessive loading could initiate localized remodeling or resorption if not properly controlled.

Clinically, the integration of finite element modeling provides a predictive framework for optimizing orthodontic anchorage design, improving safety margins, and individualizing treatment according to bone density and anatomical morphology.

Beyond mechanical optimization, the stable and minimally invasive use of mini implants has positive implications for oral function, aesthetics, and patient mental wellbeing, contributing to reduced anxiety and improved overall quality of life.

CONFLICT OF INTEREST AND FUNDING

The authors declare that there is no conflict of interest and they received no specific funding.

ARE WOMEN LESS WILLING TO CHANGE? THE INFLUENCE OF STRESS, ANXIETY AND DEPRESSION IN GASTROINTESTINAL SYMPTOMS. (Abstract) The nutritional profile of an individual constitutes one of the main regulators of gastrointestinal physiology and psychological well-being. This study **aimed** to identify the presence of gastrointestinal symptoms in medical students, health-related behaviors, and their relationship with the presence of stress, anxiety, and depression. **Materials and methods**: a total of 152 students from all years of study were included in the study. The respondents had to fill in an online questionnaire. Sociodemographic and medical related data as well as information about diet, nutritional status, quality of life and health-related behaviors were gathered. Psychological status was assessed using the *DASS-21*. Eating habits were evaluated using the *Rapid Eating Assessment for Participants*, while gastrointestinal symptom severity and impact on daily life were measured using the *Visual Analogue Scale for Irritable Bowel Syndrome* (VAS-IBS). Statistical analyses were performed using *IBM Statistical Package for Social Sciences* (*SPSS*) Statistics for Windows, version 24 (SPSS Inc., Chicago, IL, USA). **Results**: The mean age of participants was 21.28 ± 1.93 years (range: 18-25). More than half stated that they noticed changes in digestion when experiencing fatigue or poor sleep, with frequent changes observed in 27.6% of participants (N = 42). Most participants showed normal levels of stress (88.2%), depression (75%), or anxiety (74.3%). The results on the Food Sufficiency subscale revealed that most participants (71.71%, N = 109) did not eat enough, and did not have an adequate intake of daily meals, proteins, and calcium-rich foods. Additionally, the results of the Healthy Eating subscale showed that most participants (93.4%, N = 142) had insufficient consumption of healthy foods. In contrast, the results on the Low Nutrient Density Foods subscale showed that most participants (88.81%, N = 135) reported limited consumption of foods with low nutritional density, and therefore a more favorable eating behavior. Women demonstrated significantly lower results in terms of willingness to change (M = 1.71 ± 0.68) compared to men (M = 2.00 ± 0.75). **Conclusions**: The data obtained indicated that stress is the main predictor of the severity of gastrointestinal symptoms, while food sufficiency exerted a protective effect. A more adequate diet was associated with reduced symptoms of Irritable Bowel Syndrome. These results show the importance of psychological factors and the quality of food in the quality of life of the young population. **Keywords:** STRESS, ANXIETY, DEPRESSION, MEDICAL STUDENTS, GASTROINTESTINAL SYMPTOMS, SLEEP, DIET, NUTRITIONAL STATUS, PHYSICAL ACTIVITY.

INTRODUCTION

Contemporary psychobiological research has increasingly explored the bidirectional relationship between mental health and somatic functioning, with particular emphasis on the mechanisms underlying the gut-brain axis (1-3). This axis represents a neurohormonal network that connects the enteric nervous system with the central nervous system and provides a psychological framework for the recurrent comorbidity identified between psychological distress and gastrointestinal dysfunction (4). The prevalence of mental health issues is rising in the young adult population, and the mechanisms by which these psychological factors manifest as physical symptoms remain multifactorial. Psychological distress is most commonly operationalized through stress, anxiety, and depression, each exerting specific physiological effects on gastrointestinal homeostasis. Stress, characterized as an integrated physiological and psychological response to actual or perceived threats, involves the central nervous system response. Chronic or excessive activation of key brain regions contributes to emotional dysregulation, excessive visceral sensitivity and disturbances in gastrointestinal function (5).

Although anxiety is a natural adaptive response to stress, when it becomes persistent, excessive, or disproportionate, it may develop into an anxiety disorder, one of the most prevalent classes of mental health conditions worldwide (6). In 2021, it affected more than 359 million people, with a notably higher prevalence in women than in men. Similarly, depression affected approximately 332 million people in the same year, being 1.5 times more common in women than in men (7). The development of both depression and anxiety disorders is influenced by a multifactorial interplay between biological, psychological, social, and environmental factors. Consequently, these affective disturbances interact with the gastrointestinal system through specific neuroimmune pathways, linking psychological dysregulation to somatic impairments.

Growing evidence indicates that this association is modulated by modifiable lifestyle factors such as nutritional habits, sleep quality, and physical activity (8-10). The nutritional profile of an individual represents one of the main regulators of gastrointestinal physiology and psychological well-being. Contemporary dietary patterns among young adults frequently exhibit a "Westernized" profile, characterized by high intake of processed foods, with limited nutrient density (11). Despite high caloric consumption, these dietary patterns remain deficient in essential macro- and micronutrients required for proper nervous system functioning. Furthermore, the consumption of vegetables and cereal products rich in dietary fiber and essential nutrients remains insufficient (12). Increasing evidence suggests that adequate nutrient intake exerts a protective effect against systemic inflammation while preserving gastrointestinal motility and function (13).

In contrast, the consumption of low-quality food has been associated not only with the exacerbation of functional gastrointestinal symptoms but also with the intensification of anxiety and depressive states through neuroimmune pathways. Consequently, diet may function as a critical mediator whereby psychological distress may promote maladaptive eating behaviors, ultimately undermining gastrointestinal health and creating a vicious cyclic

pattern (14). However, nutrition must be considered within the broader framework of lifestyle-related health determinants. The prevalence of physical inactivity and sleep disturbances has increased in recent decades, with both factors demonstrating independent and codependent associations with obesity and alterations in gut microbiota composition (15, 16). According to Zhu and Huang (17), a physiological state of sleep improves metabolism and immunity, whereas sleep deprivation promotes hyperalgesia, affecting neurobiological systems and mediators that simultaneously impair emotional regulation.

Similarly, physical activity modulates autonomic nervous system balance and the endocrine responses. Sedentarism has been associated with increased sympathetic activity, anxiety, depression and gastrointestinal dysfunction vulnerability (18). Despite extensive research examining these factors individually, integrative approaches that evaluate the synergistic effects of sleep, diet, and physical activity in relation to stress, anxiety, and depression-and their cumulative impact on gastrointestinal health in non-clinical populations-remain underdeveloped.

In recent years, dysregulation of the bidirectional brain-gut axis has been increasingly recognized as a central framework for understanding the pathophysiology of Irritable Bowel Syndrome (IBS), which is characterized by abnormal functioning of the enteric, autonomic, and central nervous systems (19). The comorbidity between IBS and psychiatric diseases, such as anxiety and depression, has been individualized in up to 60% of patients (20). While the connection between Irritable Bowel Syndrome and stress is well documented through its impact on the intestinal sensitivity, secretion, motility, and permeability, the behavioral pathways underpinning this association require further elucidation. The extent to which negative emotional states affect gastrointestinal health directly or through mediated changes in lifestyle habits remains insufficiently understood. A thorough understanding of these dynamics is essential for the development of holistic health strategies aimed at the 18 to 25-year-old population. The present study aimed to characterize the multidimensional interplay between lifestyle behaviors, psychological functioning and gastrointestinal health in a young adult population. The central aim was to evaluate the extent to which dietary behaviors, defined by both nutrient sufficiency and dietary quality, mediate the impact of psychological distress on the intensity of gastrointestinal symptoms.

MATERIALS AND METHODS

Study Population. The participants were selected using the snowball method between. The study was developed during October and November 2025. The inclusion criterion in the study was the completion of the questionnaire before the submission deadline. Questionnaires were distributed to medical science students, from all years of study. The respondents were informed about the purpose of the research and the use of the collected data. No incentives were offered. Finally, 152 questionnaires were included in the study.

Data collection. The questionnaire was constructed using Google Forms (Alphabet, Mountain View, CA, USA).

a. The first part of the questionnaire collected socio-demographic and lifestyle-related data (such as age, gender, environment of origin, Body Mass Index - BMI, religion, adherence to religious fasting

practices, smoker/non-smoker status, consumption of psychoactive substances, number of hours of sleep per night, self-assessment of sleep quality, and engagement in physical activities).

b. The second section of the questionnaire included information about the participants' health status (diagnosis of gastroesophageal reflux disease, irritable bowel syndrome, and respiratory, gastric, or intestinal infections, as well as the frequency of medication use. Information was also collected regarding the use of medication or dietary supplements, such as antibiotics, magnesium, zinc, vitamin E, supplements, B vitamins, and omega-3/omega-6 supplements. Additionally, the participants reported the type of diet they followed, including Mediterranean, DASH, Nordic, Japanese, traditional Romanian, keto, oligoantigenic, or vegetarian/vegan diet.

c. The third section included a psychological questionnaire designed to measure negative emotional states which can have a major influence on the health status of the participants - *DASS-21* (21). The questionnaire was a set of three self-rating scales that indicated the severity of core symptoms in the domains of depression, anxiety, and stress. The DASS score was calculated by summing the responses to the items of each subscale, with each item rated on a Likert scale from 0 (“Not at all”) to 3 (“Applied very much or almost all of the time”).

d. The next part of the questionnaire used a tool that quickly assessed the participants' eating habits - *Rapid Eating Assessment for Participants, 21 questions - REAP v.2* (22). This instrument is an updated and validated dietary screener designed to quickly assess a patient's eating behaviors, dietary patterns, and readiness to change. The questionnaire included five subscales: Food Sufficiency, Healthy Eating, Intake of Low-Nutrient Foods, Exercise and Willingness to Change. The response options were "Every day", "More than two times a week" or "More than three times a week" (depending on the item), "Two or fewer times a week" or "Three or fewer times a week" and "Never". The score assigned to the response options ranged from 0 to 3 points. The highest possible score for REAP v.2 is 60 points. Although higher numbers generally represent healthier habits, a given person might be high on one subscale and low on another.

e. The final part of the survey included a self-report tool designed to measure the severity of gastrointestinal symptoms and their impact on a patient's life - *The Visual Analogue Scale for Irritable Bowel Syndrome (VAS-IBS)* (23). It consists of seven visual analogue scales assessing pain, diarrhea, constipation, bloating, vomiting/nausea, psychological well-being, and the influence of intestinal symptoms on daily life. Each item received a score from 1 (*maximum perceived severity*) to 10 (*absence of symptoms*). Two additional items, if the subject experienced defecation urgency or a sensation of incomplete evacuation when defecating (*yes* or *no*).

In addition, at the end of the questionnaire, several items were added to assess whether certain foods had a perceived negative effect on the diet, and which ones, whether changes in digestion were observed when participants were tired or slept poorly, as well as digestive symptoms that occurred during stressful periods.

Statistical analysis. All statistical analyses for this research were performed using *IBM Statistical Package for Social*

Sciences (SPSS) Statistics for Windows, version 24 (SPSS Inc., Chicago, IL, USA). Results for descriptive statistics were expressed as means and standard deviations (SD).

The normality of data distribution was tested using the Kolmogorov-Smirnov test. Given that the data were partially normally distributed, parametric tests were applied. To assess the comparative results considering gender and diagnosis of a chronic disease, the Independent Sample t-Test was performed.

Pearson's correlation coefficient was used to test the relationship between variables. A p-value < 0.05 was considered statistically significant. A multiple mediation analysis was also conducted to explore the role of Food Sufficiency and Low-Density Nutrient Foods as mediators between stress and gastrointestinal symptoms. The PROCESS procedure for SPSS, developed by Andrew F. Hayes, was used to test this model. The statistical significance threshold was set at $p < 0.05$, which ensured a rigorous interpretation of the results.

Ethical approval. The study was conducted in accordance with the Declaration of Helsinki, and the protocol was approved by the Ethical Committee of Prolife Clinics Iași, Romania, No.74/03.07.2025.

RESULTS

Socio-demographic and lifestyle-related data

The participants aged M = 21.28 ± 1.93, with ages ranging from 18 to 25 years. Most participants were women (76.3%, N = 116) and more than a half originated from urban areas (66.4%, N = 101).

Regarding weight status calculated according to Body Mass Index (BMI), more than half of the participants had a normal weight (63.8%, N = 97), less than one quarter were overweight (23%, N = 35), and a smaller proportion (9,9%, N = 15) were underweight, with BMI values below the WHO limit of 18.5 kg/m^2. The results showed that most participants were Orthodox Christians (78.9%, N = 120). More than half said they did not fast (63.8%, N = 97), while one quarter reported adherence to Orthodox Christian fasting periods (25.7%, N = 39). More than half of the participants were non-smokers (56.6%, N = 86), whereas one quarter declared that they smoked daily (25%, N = 38). Most of the participants did not consume psychoactive substances (90.8%, N = 138), while a small proportion consumed them occasionally (8.6%, N = 13). More than half of the participants reported sleeping between 5 and 7 hours per night (63.8%, N = 97) and more than a quarter slept between 7 and 9 hours per night (25.7%, N = 39). The quality of sleep during the night described by most participants was: "I sleep well, but sometimes I wake up" (50%, N = 76), "I sleep very well, without interruptions" (25%, N = 38), "I am a light sleeper and wake up often" (11.8%, N = 18).

Regarding physical activity, nearly half of the participants reported engaging in light physical activity occasionally (48.7%, N = 74), while one third reported performing moderate physical activity several days a week (30.3%, N = 46).

Participants' health, digestion and diet status

The participants were asked about whether they had ever been diagnosed with any diseases related to the digestive system. Most participants reported no such diagnoses. However, a small proportion had been diagnosed with gastroesophageal

reflux disease (7.2%, or 11 people) or irritable bowel syndrome (3.9%, or 6 people). Additionally, over one quarter of the participants (27.6%, N = 42) reported at least one episode of respiratory, gastric, or intestinal infection.

Regarding the use of medications and supplements, less than half of the participants (47.4%, N = 72) reported that they rarely used medications for any condition, while over one quarter reported monthly use (26.3%, N = 40). Within the previous 12 months, less than half of the participants reported antibiotic use (46.1%, N = 70). More than half of the participants used Magnesium supplements (52.6%, N = 80), and one third of the participants used Zinc supplements (33.6%, N = 51), B vitamins (35.5%, N = 54) or omega-3/omega-6 supplements (31.6%, N = 48). Vitamin E supplements were consumed by a small part of the participants (17.1%, N = 26).

Approximately one third of the participants reported following a traditional Romanian diet (31.6%, N = 48). Smaller proportions reported adherence to other diets: 9.9% (N = 15) followed a Vegetarian or Vegan diet, 7.9% (N = 12) chose a Mediterranean diet, and 3.9% (N = 6) consumed a Nordic diet.

Participants were asked whether there were certain foods that clearly affected their digestion. Responses were distributed as follows: about one third said “never” (31.6%, N = 48), more than one quarter answered “yes, definitely” (25.7%, N = 39), and less than one quarter answered “sometimes” (23.7%, N = 36). Foods that triggered digestive disorders included dairy products (9.2%, N = 14), fast food and pastries (8.55%, N = 13), some fruits and vegetables such as bananas, tomatoes, peas, beans (6.57%, N = 10), but also sweetened or fizzy drinks (3.28%, N = 5).

Over half of the participants reported experiencing noticeable changes in digestion when they were fatigued or had insufficient sleep, with such changes occurring frequently (27.6%, N = 42) or occasionally (29.6%, N = 45). In addition, during stressful periods, participants manifested various digestive symptoms, with abdominal pain (33.6%, N = 51) or bloating (26.3%, N = 40) being the most commonly reported.

Depression, Anxiety, Stress Scale (DASS-21)

The scale demonstrated very good internal consistency, as determined by Cronbach’s alpha of 0.96. Analysis of the distribution of scores on the DASS-21 showed that approximately half of the participants had a normal level of stress (54.6%), depression (49.3%), or anxiety (44.1%) (tab. I).

TABLE I.
DASS-21 Severity Classification

	Normal	Mild	Moderate	Severe	Extremely severe
Stress	83 (54.6%)	21 (13.8%)	21 (13.8%)	14 (9.2%)	13 (8.6%)
Depression	75 (49.3%)	7 (4.6%)	40 (26.3%)	8 (5.3%)	22 (14.5%)
Anxiety	67 (44.1%)	16 (10.5%)	30 (19.7%)	11 (7.2%)	28 (18.4%)

Frequency and percentages (%)

Rapid Eating Assessment for Participants (REAP)

The Cronbach Alpha score was 0.54 for the total scale, 0.48 for *Food Sufficiency subscale*, 0.56 for *Healthy Eating Pattern subscale* and 0.66 for *Low Nutrient Density Foods subscale*. For these REAP subscales, as well as for the items related to *Physical Activity* and *Disponibility to Change* we obtained the following results:

a. food sufficiency - M = 6.24 ± 2.45,
b. healthy eating pattern - M = 9.16 ± 3.22,
c. low nutrient density foods - M = 21.93 ± 3.66,
d. physical activity - M = 2.30 ± 0.92,
e. disponibility to change - M = 1.78 ± 0.71.

The total REAP score was on average M = 39.61 ± 5.98, with scores ranging from 21 (1.3%, N = 2) to 57 (0.7%, N = 1).

The results on the Food Sufficiency subscale indicated that most participants (71.71%, N = 109) did not eat enough, and did not have an adequate intake of daily meals, proteins and calcium-rich foods. Similarly, results on the Healthy Eating subscale showed that most participants (93.4%, N = 142) reported insufficient consumption of healthy foods. In contrast, the results on the Low Nutrient Density Foods subscale showed that most participants (88.81%, N = 135) demonstrated reduced consumption of foods with low nutritional density, indicating a more favorable eating behavior.

The Visual Analogue Scale for Irritable Bowel Syndrome (VAS-IBS). The total score for the VAS-IBS scale was M = 53.59 ± 14.44, with values ranging from 10 (0.7%, N = 1) to 70 (10.5%, N = 16). Thus, the participants reported a low severity of gastrointestinal symptoms and a relatively good quality of life.

Regarding the response to the last two items of the instrument, less than one quarter of the participants (23.7%, N = 36) stated that they had felt an urgency to defecate in the previous 2 weeks, and less than half of the participants (43.4%, N = 66) reported a sensation of incomplete bowel evacuation. The scale had good internal consistency, as determined by Cronbach's alpha of 0.86.

Comparative and correlational analysis. The independent samples t-test revealed the existence of significant gender differences in Body Mass Index of the participants ($t(150) = 4.15$, $p < 0.001$), with women exhibiting significantly lower BMI values (M = 21.98 ± 3.74) compared to men (M = 24.99 ± 3.96). In addition, significant differences were also identified in terms of the participants' willingness to change ($t(150) = 1.51$, $p = 0.03$). Women had significantly lower results in terms of willingness to change (M = 1.71 ± 0.68) compared to men (M = 2.00 ± 0.75).

Significant differences were identified between participants who received a positive diagnosis and those who did not have a diagnosis of irritable bowel syndrome in terms of physical activity levels ($t(150) = -2.17$, $p = 0.03$). Thus, those who were diagnosed with irritable bowel syndrome had a lower physical activity score (M = 1.50 ± 1.04), compared to those who did not have this condition (M = 2.33 ± 0.91).

The results of the comparative analysis showed that there were significant differences for the variable "positive/negative diagnosis for irritable bowel syndrome" in terms of stress ($t(150) = 3.84$, $p < 0.001$), depression ($t(150) = 4.27$, $p < 0.001$) and anxiety levels ($t(150) = 4.36$, $p < 0.001$),

meaning that those with a positive diagnosis had a significantly higher score on all these psychological scales (M = 31.00 ± 11.91 for stress, M = 35.66 ± 18.39 for depression, respectively 26.66 ± 14.62 for anxiety) compared to those without this diagnosis (M = 14.53 ± 10.22, M = 13.19 ± 12.37, respectively 9.89 ± 8.98). The independent samples t-test indicated the existence of significant differences between participants who received a positive diagnosis and those who did not have a diagnosis of irritable bowel syndrome in terms of VAS-IBS scale results ($t(150) = -2.17$, $p = 0.03$). Thus, those who were diagnosed with irritable bowel syndrome had a lower VAS-IBS score (M = 33.67 ± 12.48), compared to those who did not have this condition (M = 54.40 ± 13.96).

Significant differences were identified between participants who consumed and those who did not consume antibiotics in terms of their willingness to change ($t(150) = 2.48$, $p = 0.01$). Those who reported antibiotic use in the previous 12 months demonstrated a significantly higher score on readiness for change (M = 1.93 ± 0.80) than those who did not report antibiotic use (M = 1.65 ± 0.59).

The results of the comparative analysis showed that there were significant differences for the variable “consumption of antibiotics" in terms of depression ($t(150) = 2.09$, $p = 0.03$) and VAS-IBS score ($t(150) = - 2.76$, $p = 0.007$). Thus, those who had taken antibiotics in the previous 12 months had a significantly higher score on depression (M = 14.65 ± 12.86) than those who had not ((M = 10.75 ± 10.10).

Moreover, those who had taken antibiotics in the previous 12 months had a lower score on the VAS-IBS scale and therefore, a greater severity of irritable bowel syndrome symptoms (M =50.06 ± 16.60) compared to those who had not taken antibiotics (M = 56.60 ± 11.52).

The Pearson correlational analysis found a significant positive association between age and number of hours slept per night ($r = 0.17$, $p = 0.03$), indicating that older participants tended to report longer sleep duration.

The number of hours of sleep correlated negatively with the level of depression ($r = -0.19$, $p = 0.01$), meaning that increased nighttime sleep was associated with lower reported depression. Additionally, there were positive correlations between the number of hours of sleep per night and the scores on the REAP instrument subscale for Low Density Nutrient Foods ($r = 0.17$, $p = 0.03$), suggesting that longer sleep duration was linked to a greater tendency to consume foods low in nutritional density, such as fatty meats, solid fats, sweetened beverages, sweets, and processed snacks. The REAP section on Food Sufficiency correlated negatively with levels of stress ($r = -0.40$, $p < 0.001$), depression ($r = -0.43$, $p < 0.001$), and anxiety ($r = -0.42$, $p < 0.001$), meaning that the more satisfactory the diet, the lower the levels of stress, depression, and anxiety, respectively. Furthermore, Food Sufficiency correlated positively with gastrointestinal symptoms - as measured by VAS-IBS ($r = 0.36$, $p < 0.001$), indicating that the more satisfactory the diet, the less severe the gastrointestinal symptoms and the better the quality of life.

The REAP section on Low Nutrient Density Foods correlated negatively with levels of stress ($r = -0.22$, $p = 0.006$), depression ($r = -0.20$, $p = 0.10$), and anxiety ($r = -0.23$, $p = 0.003$), meaning that the more the participants consumed foods with low nutritional density, the lower the levels

of stress, depression, and anxiety, respectively. In addition, Low Nutrient Density Foods correlated positively with gastrointestinal symptoms ($r = 0.21$, $p = 0.007$), meaning that the more the participants consumed foods with low nutritional density, the less severe the gastrointestinal symptoms.

There was a negative correlation between the level of physical activity measured using the REAP instrument and the level of anxiety ($r = -0.20$, $p = 0.01$), indicating that the higher the level of physical activity, the lower the anxiety. The level of physical activity correlated positively with gastrointestinal symptoms ($r = 0.22$, $p = 0.005$), meaning that the more the participants exercised, the less severe the gastrointestinal symptoms were.

Readiness to change within the REAP instrument correlated negatively with gastrointestinal symptoms ($r = -0.21$, $p = 0.009$), meaning that the greater the participants' willingness to change their eating behavior, the greater the tendency for the severity of gastrointestinal symptoms to increase. A negative correlation existed between willingness to change and Food Sufficiency ($r = -0.21$, $p = 0.009$), meaning that the more interested the participants were in changing their eating behavior, the more their diet was less satisfying. In addition, willingness to change correlated positively with anxiety levels ($r = 0.24$, $p = 0.003$), meaning that the more the participants were interested in changing their eating behavior, the higher their anxiety levels.

A negative correlation was identified between anxiety levels and gastrointestinal symptoms ($r = -0.66$, $p < 0.001$), meaning that the higher the anxiety level, the greater the severity of gastrointestinal symptoms. In addition, the level of stress ($r = -0.59$, $p < 0.001$) and depression ($r = -0.60$, $p < 0.001$) correlated negatively with gastrointestinal symptoms, indicating that the higher the stress and depression levels, the greater the severity of gastrointestinal symptoms.

Mediation analysis. A mediation analysis was conducted to test the mechanisms by which stress level influences the severity of digestive symptoms, considering several potential mediators, represented by the REAP subscales (Food Sufficiency, Low Nutrient Density Foods). The associations between the variables involved have already been analyzed. Thus, significant correlations were found between the two variables:

a. food sufficiency was negatively associated with stress levels ($r = -0.40$) and positively associated with the severity of digestive symptoms ($r = 0.36$);
b. stress level was negatively associated with gastrointestinal symptomatology ($r = -0.59$);
c. low nutrient density foods was positively associated with gastrointestinal symptomatology ($r = 0.21$) and negatively with stress level ($r = -0.22$).

Linear regression analysis revealed the following results:

a. stress significantly predicted digestive symptoms ($\beta = -0.10$, $p < 0.001$);
b. stress significantly predicted food sufficiency ($\beta = -0.09$, $p < 0.001$);
c. stress predicted low nutrient density foods ($\beta = -0.05$, $p = 0.048$);
d. food sufficiency did not predict low nutrient density foods ($\beta = 0.19$, $p = 0.13$);

e. low Nutrient Density Foods did not predict digestive symptoms (β = 0.29, p = 0.27).

The data obtained indicated that stress was the main predictor of the severity of gastrointestinal symptoms. Food Sufficiency had a protective effect: a more adequate diet was associated with reduced symptoms of Irritable Bowel Syndrome (IBS). Low Nutrient Density Foods did not significantly contribute to gastrointestinal symptomatology in the presence of other variables.

In conclusion, the model did not support full serial mediation, but clearly supported simple mediation through Food Sufficiency. Although stress had a strong direct effect on IBS symptomatology, part of this effect was explained by changes in basic eating behavior.

While Food Sufficiency was found to mediate the effects of stress, similar analyses for anxiety and depression did not reveal any notable indirect effects. However, both anxiety and depression were significantly associated with gastrointestinal symptom severity, supporting their relevant role in the pathogenesis of IBS, through predominantly direct mechanisms. This suggests the involvement of distinct psychobiological mechanisms, independent of diet, in the relationship between anxiety, depression and gastrointestinal symptom severity.

DISCUSSION

This study investigated the multifactorial correlation between lifestyle factors, with particular emphasis on nutritional habits, psychological well-being, gut health and mental health. The results characterize a vulnerability profile in which psychological distress functions as a central catalyst for both maladaptive eating behaviors and functional somatic symptomatology.

Data analysis revealed that different psychological factors exert a distinct influence on gastrointestinal health. While stress was identified as a direct predictor of gastrointestinal symptom severity, mediation analysis indicated that a portion of this effect was accounted for by changes in eating behavior, specifically Food Sufficiency. This implies that stress-related changes in nutrition can play a role in exacerbating gastrointestinal symptoms. Similar patterns have been observed in broader mental health studies. Madison and Kiecolt-Glaser (2019) reported that stress and depression affect gastrointestinal function both directly and indirectly through diet related behaviors (24). However, in our study, an indirect dietary influence, especially food insufficiency, was observed exclusively for stress, with no significant mediation identified for depression.

In contrast, anxiety and depression were predominantly associated with gastrointestinal symptoms through direct psychological mechanisms. These findings underscore the potential role of the neural and endocrine pathways of the gut-brain axis. Rathore *et al. (*2025) also showed in their comprehensive review that anxiety and depression affect gastrointestinal function directly through gut-brain axis mechanisms, highlighting processes beyond dietary modulation (25). Moreover, this result is consistent with the Biopsychosocial Model of IBS, suggesting that anxiety, particularly, may induce direct physiological changes, including visceral hypersensitivity and vagus nerve mediated motility alterations. (26).

Diet quality has been found to be associated with mental disorder severity

through different pathways. Participants with adequate nutrient intake reported lower levels of stress, anxiety, and depression while also having less severe gastrointestinal symptoms, demonstrating the protective effect of Food Sufficiency. This result may reflect the contribution of essential nutrients in regulating neurotransmitter pathways and systemic inflammation, both central to maintaining emotional regulation and gut homeostasis. In contrast, increased consumption of low-density foods corresponded with lower stress levels and decreased anxiety and depression symptomatology in our sample. This particular finding diverges from the results of Sparling *et al.* (2025) and Solomou *et al*. (2023) who reported that both the consumption of low nutrient quality foods and food insufficiency are associated with higher levels of stress, anxiety and depressive symptoms (27, 28).

This discrepancy can be explained by the study design and outcome assessment. Prior studies have focused on long-term dietary patterns, whereas this study reflects a short-term emotional regulation through palatable, calorie-dense foods, illustrating the correlation with the "comfort food" phenomenon. According to Gemesi *et al.* (29), most stress-eaters are particularly enjoying low nutrient foods such as cookies, fast-food, chocolate, while almost 70% of them are overeaters.

A comparison by sex revealed that women exhibit a lower Body Mass Index and lower reported willingness to change than men. The significant gender differences in terms of BMI are consistent with the Tack SHS survey across 12 European countries, which reported a 25.7 kg/m² BMI for men compared with 25.0 kg/m² for women (30). Our finding regarding higher willingness to change among men is in contrast with previous results, which suggests that women are generally more concerned with diet and weight control (31-32). The observed pattern may be explained by the fact that the women in the sample may view their current eating behaviors as adequate by correlating them with a lower BMI. On the other hand, men may be more inclined to acknowledge the need for lifestyle changes associated with elevated BMI values. The result can be determined by several factors: socio-demographic (the young women included in the study are 18-25 years old, which favors a good level of health), medical (the BMI level is comfortable) and socio-cultural (the young women value health, declared that they diet and are concerned about a healthy lifestyle, a fact proven by the researched variables, such as sleep, nutrition, physical activity, lifestyle, etc.) that make them less willing to change because they fill comfortable and satisfied with their body-image.

A key finding of the current study is the strong correlation between irritable bowel syndrome (IBS) and increased psychological burden. Participants with IBS scored significantly higher on the measures of stress, anxiety, and depression. These findings are concordant with the established concept of a “vicious cycle” of functional gastrointestinal disorders. This concept suggests that the unpredictability of symptoms exacerbates psychological distress and perpetuates condition severity (33).

Furthermore, patients with IBS reported lower VAS-IBS scores, reflecting both greater symptom severity and lower perceived quality of life in individuals without a clinical diagnosis. Both the participants with or without IBS stated that they manifested digestive symptoms such as ab-

dominal pain and bloating during stressful periods, which reinforces the idea of an immediate correlation between stress and intestinal function.

Individuals from our study who reported antibiotic consumption in the last 12 months revealed greater depressive symptoms and more severe gastrointestinal issues than non-users. This result confirms the causal link between antibiotic use and adverse mental health outcomes. These findings support the microbiota-gut-brain axis hypothesis, suggesting that antibiotic-induced alterations in the gut microbiome can disrupt neurochemical signaling between the gut and brain (34). Consistent with our results, this group also showed a higher willingness to change their dietary habits, possibly reflecting a response to the symptoms associated with post-antibiotic dysbiosis.

While our research individualizes a negative relationship between mental health and antibiotic use, a study by Dinan and Dinan (35) presents a nuanced perspective on these effects. They highlighted that certain antibiotics may have antidepressant effects by modulating neuroinflammation, microglial activity, and monoamine levels, whereas other antibiotics can negatively influence mental health by reducing microbial diversity, compromising intestinal barrier integrity, and promoting inflammation. This discrepancy can be attributed to differences in antibiotic type, dosage, and context of administration, as our sample primarily included participants using antibiotics for common short-term infections, whereas the positive antidepressant effects described in their review were associated with specific antibiotics administered in controlled clinical or experimental contexts.

Sleep is an important modulator of the gut-brain axis, and our study revealed a negative correlation between sleep duration and depression, confirming prior research on sleep deprivation and mood dysregulation. Sleep disturbances may disrupt the hypothalamic-pituitary-adrenal axis, resulting in a higher stress level, increased intestinal permeability, and intestinal dysbiosis, all leading to higher susceptibility to depressive symptoms (36).

The positive correlation between Low Nutrient Density Foods and longer sleep hours is a paradoxical finding from our study that can be explained by the lifestyle patterns of young adults. Participants might be sleeping more hours in total, but the irregularity of the sleep pattern might contribute to poorer nutritional choices through a specific craving for high-sugar, high-fat foods to provide a quick energy boost, implying that a disrupted circadian rhythm can influence the brain and conduct to an increased activation in reward centres. Our results are congruent with those in the scientific literature, which generally highlights a complex bidirectional relationship (37-38). Moreover, a vast majority of the participants stated that their sleep affected their digestion, which may reflect interconnected effects involving sleep, gastrointestinal function, mental health, and dietary habits.

Another indispensable lifestyle factor, physical activity was associated with lower anxiety levels and gastrointestinal symptoms. This can be explained by both the enhancement of vagal tone, reducing the level of stress and the release of anti-inflammatory cytokines during activity, decreasing systemic inflammation associated with anxiety and IBS (39). This observation was further supported by the finding

that participants diagnosed with IBS had significantly lower levels of physical activity. Sedentarily deprives IBS patients of stress-relieving and motility-regulating benefits, creating a detrimental cycle and aggravating their condition.

Strengths and limitations of the study. This is one of the few studies that conducted an integrative analysis of the synergistic effects of lifestyle factors in relation to the gut-brain axis in a young Romanian adult population. Certain limitations of this study need to be acknowledged. First, the sample consisted predominantly of young women and the results were not fully generalizable to the male population or to other age groups. Second, this research has a cross-sectional design, which prevents the establishment of a causal relationship between the factors and the somatic response. Additionally, reliance on self-reporting can lead to overestimated or underestimated correlation, recall bias and social desirability bias. Another limitation is the unmeasured confounders, such as genetic predisposition, early childhood trauma, or the specificity of the antibiotics used by the participants. Furthermore, the REAP v.2 scale and its subscales had a low internal consistency in this study, with Cronbach's alpha ranging from 0.48 to 0.66.

This could be attributed to the relatively modest sample size (N = 152) or nuanced dietary patterns in this demographic group. For a more comprehensive understanding, future studies should extend this research to clinical populations and investigate whether the observed mediation effects persist over time.

CONCLUSIONS

This study points the importance of healthy eating habits and behaviors in the young population. Stress management, depression anxiety and the adoption of a healthy diet were highlighted as important at this age. These results reflect the importance of educating young people about healthy practices and highlight the impact of psychological balance on physical health.

EXPLORING THE EFFECTS OF PEPSIN ON SALIVARY PEPTIDOME: INSIGHTS FROM A PROOF-OF-CONCEPT PROTEOMIC PROFILING STUDY USING MALDI-ToF MASS SPECTROMETRY (Abstract): Pepsin, a component of gastric refluxate, has been investigated as a potential salivary biomarker for gastro-esophageal reflux disease (GERD), although its diagnostic accuracy remains uncertain. This proof-of-concept study aimed to characterize the effects of pepsin on the human salivary peptidome using matrix-assisted laser desorption/ionization-time of flight (MALDI-ToF) mass spectrometry. **Materials and methods:** Whole saliva samples were collected from ten healthy adult volunteers under fasting conditions and divided into untreated controls and aliquots digested with pepsin at acidic pH. MALDI-ToF MS was used to profile digestion-induced changes in peptide mass patterns. Spectral data were analyzed using multivariate statistical approaches, including principal component analysis (PCA), linear discriminant analysis (LDA), and hierarchical clustering. **Results:** Pepsin digestion increased peptide signal intensity and spectral complexity compared with controls. PCA demonstrated clear separation between native and digested samples along the first principal component. Ten peptide m/z features showed the strongest association with pepsin exposure based on PCA loadings. LDA and hierarchical clustering further supported this distinction, with the top 15 discriminative m/z features showing consistent enrichment in digested samples despite inter-individual variability. **Conclusions:** Pepsin exposure induces reproducible remodeling of the salivary peptidome detectable by MALDI-ToF MS. Although this peptide-level approach cannot resolve the full diversity of salivary proteoforms, the resulting signatures support the feasibility of identifying markers of reflux-associated enzymatic activity and provide a basis for future validation in clinical GERD cohorts. **Keywords:** SALIVARY PEPTIDOME, MALDI-ToF MASS SPECTROMETRY, PEPSIN DIGESTION, GASTRO-ESOPHAGEAL REFLUX DISEASE, PEPTIDE BIOMARKERS.

INTRODUCTION

Gastroesophageal reflux disease (GERD) is one of the most commonly encountered gastrointestinal disorders in clinical practice, with a notable global prevalence estimated to exceed 20% in Western

countries (1). Studies have shown that individuals with reflux disease experience a significant reduction in health-related quality of life compared to the general population, irrespective of the severity of endoscopic findings (2). It poses a significant burden on healthcare systems worldwide, requiring substantial resources in order to manage and treat effectively (3). Currently, ascertaining a GERD diagnosis often relies on performing a series of invasive and expensive procedures, such as upper gastrointestinal endoscopy or ambulatory pH-impedance monitoring (4). However, these methods are hindered by relatively high costs, limited accessibility in some settings, and the requirement for specialized expertise to accurately interpret the findings (5). In this context, there is a growing need for reliable non-invasive diagnostic biomarkers that could aid in the diagnosis of this condition.

Saliva, a readily accessible biofluid, has been proposed as a potential source of biomarkers for GERD. To that end, many studies investigated the use of salivary pepsin as a diagnostic test, a digestive enzyme secreted by gastric chief cells and key factor in tissue injury (6). However, currently there is a lack of consensus regarding optimal collection methods, processing techniques, and timing for measuring salivary pepsin, with varying reports regarding its diagnostic accuracy (7). While the presence of salivary pepsin has been investigated as a diagnostic biomarker in itself, less focus has been placed on its biological effects on the salivary proteome (8). Given pepsin's potent proteolytic activity under acidic conditions, reflux events may be associated with a characteristic salivary peptide pattern that persists beyond the transient presence of the enzyme itself.

The rapid advances in proteomic technologies provide an opportunity to examine these effects in more detail, broadening the avenues of non-invasive diagnostics (8, 9). Matrix-Assisted Laser Desorption/Ionization-Time of Flight (MALDI-ToF) mass spectrometry is a robust analytical technique widely used for rapid and precise profiling of peptide and protein mass patterns. Owing to its sensitivity and reproducibility, it represents an appropriate approach for characterizing the salivary peptidome and for exploring potential biomarkers relevant to GERD.

In this proof-of-concept study, we investigated the effects of pepsin exposure under acidic conditions on the human salivary peptidome using MALDI-ToF mass spectrometry. Rather than focusing on the detection of salivary pepsin itself, our approach aimed to characterize the proteolytic peptide signatures generated by *pepsin* activity. Identifying reproducible peptide patterns may provide insights into reflux-related enzymatic effects and advance the discovery of potential non-invasive diagnostic tools for GERD. To complement the experimental digestion, an in-silico simulation of pepsin-mediated cleavage was carried out using MS Digest, a freely available online tool of Protein Prospector program (10), providing a theoretical peptide map to support interpretation of the MALDI-ToF results.

MATERIALS AND METHODS

The study protocol received ethical approval from the Grigore T. Popa University of Medicine and Pharmacy Iași Institutional Review Board (232/13.10.2022). An overview of the study design is presented in first figure. Saliva samples were collected and divided into two preparation groups.

In the control group, samples were acidified only. In the experimental group, acidified saliva was incubated with pepsin to generate digested peptide products. In silico pepsin digestion was performed to support peptide identification. All samples were analyzed using MALDI-ToF mass spectrometry. Spectral data were interpreted and subjected to comparative analysis and pattern identification to evaluate differences between control and pepsin-digested samples (fig. 1).

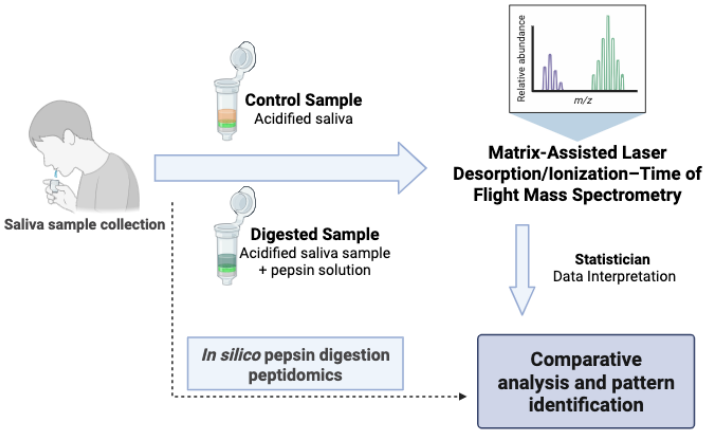

Fig. 1. Detailed workflow for salivary peptidomics analysis using MALDI-ToF mass spectrometry in silico digestion and statistical interpretation of mass spectra (created with BioRender.com).

Saliva Sample Collection

Whole saliva samples were collected from healthy volunteers (n=10) aged 20 to 30 years. Sample collection was performed in the morning following an overnight fast, in the first two hours after waking. To minimize potential contamination, participants were instructed to brush their teeth 30 minutes prior to collection, without consuming any food, beverages, or smoking afterwards. Approximately 2-3 mL of unstimulated saliva was collected in sterile tubes.

Control Samples

Control samples consisted of acidified whole saliva without the addition of pepsin, processed in parallel with the experimental samples under identical conditions, including incubation, centrifugation, desalination, and mass spectrometry analysis. This allowed for comparison to identify pepsin-specific proteolytic effects. These samples were labeled C1 through C10 to ensure consistent tracking throughout the workflow. For the subsequent digestion experiments, the saliva aliquots exposed to pepsin were labeled D1 through D10, following the same numbering scheme as their corresponding control samples.

Pepsin Treatment and Acidification

Pepsin solution (Sigma-Aldrich) was combined with saliva samples in a 1:20 ratio (pepsin to saliva). The total protein concentration in unstimulated whole saliva ranged from 2.9 to 3.1 µg/µL, consistent with values previously reported in the literature (11). Protein concentration was determined using a NanoDrop spectrophotometer (Thermo Fisher Scientific) based

on UV-Vis absorbance measurements. The instrument quantified protein levels by measuring absorbance at 280 nm, where aromatic amino acids exhibit characteristic absorption. A sample volume of 1-2 µL was used, and the Nano Drop's short-path optical system allowed direct measurement without cuvettes. Background correction was automatically applied using a reference wavelength (typically 260 nm) to ensure accurate readings for complex biological matrices such as saliva. Acidification of the samples was performed to achieve a pH range of 1-2, ensuring optimal proteolytic activity of pepsin. pH was measured using pH indicator paper, and adjustments were made using hydrochloric acid (0.1 N).

Digestion Process and Supernatant Collection

The saliva-pepsin mixtures were incubated at 37°C for 30 minutes at 450 rotations per minute (rpm) using a shaking incubator. This process was used to maximize pepsin enzymatic activity. All saliva digestion reactions were performed in technical duplicate to ensure reproducibility of the pepsin-mediated proteolysis workflow. Following digestion, samples were centrifuged at 12,000 rpm for 10 minutes and supernatant was collected.

Sample Desalination, Concentration, and Purification

Supernatant samples were desalted, concentrated, and purified using ZipTip C18 pipette tips (Millipore), following the manufacturer's protocol(12). First, the C18 tips were activated by wetting with acetonitrile (100 % ACN). Next, the tips were equilibrated with an aqueous solution containing trifluoroacetic acid (0.1% TFA). The samples were then repeatedly aspirated through the tips, allowing peptides and small proteins to bind to the C18 resin while salts and other impurities were left unbound. After binding, the tips were washed with an acidic solution (0.1% TFA) to remove residual salts and contaminants. Finally, the purified analytes were eluted (50 % ACN in 0.1% TFA), producing a desalted, concentrated solution of analytes ready for analysis by mass spectrometry. The same procedure of purification was applied to the control saliva samples.

MALDI-ToF Mass Spectrometry

MALDI-ToF MS was performed on a Bruker Ultraflex MALDI-ToF / ToF mass spectrometer equipped with a pulsed nitrogen UV laser. The instrument was operated in positive ion mode, and spectra were acquired in reflectron mode. Prior to spotting, peptide samples were mixed with super-DHB (sDHB), a matrix consisting of a 1:1 mixture of 2,5-dihydroxybenzoic acid and 2-hydroxy-5-methoxybenzoic acid, commonly used to enhance peptide ionization and improve signal homogeneity in MALDI analyses. Samples were applied onto a 384-spot stainless-steel target plate using the dried-droplet method by depositing 0.8 µL of matrix solution and 1.0 µL of sample solution, mixed directly on the target and allowed to dry at room temperature. The laser attenuation was set to 80%, and spectra were acquired using the following parameters: 20 kV acceleration voltage, 40% grid voltage, 140 ns delay, low-mass gate of 500 Da, and an acquisition mass range of 450-5000 Da. For each final spectrum, 500 laser shots were accumulated. External calibration was performed using the monoisotopic (M+H)+ ions of the following peptide standards: Bradykinin (1-7) (m/z 757.4), Angiotensin II (m/z 1046.5), Angiotensin I (m/z 1296.7), Substance P (m/z 1347.7), Bombesin (m/z 1619.8),

Renin Substrate (m/z 1758.9), ACTH (1-17) (m/z 2093.1), ACTH (18-39) (m/z 2465.2), and Somatostatin (m/z 3147.5). Theoretical monoisotopic masses were calculated using the ChemCalc online tool. Spectra were processed using Bruker FlexAnalysis 3.4 software. The MALDI ToF mass spectrometry data have been deposited to the ProteomeXchange Consortium via the PRIDE partner repository (13) with the dataset identifier PXD076267.

Statistical Analysis and Data Processing

Data processing and statistical analyses were performed using Python (version 3.9.x). Raw MALDI-ToF mass spectra were exported as CSV files and processed using a custom computational pipeline. Unsupervised Principal Component Analysis (PCA) was conducted to visualize the global variance and identify inherent clusters between the native and digested peptide profiles. To specifically identify the peptide features that best discriminate between the two conditions, a supervised Linear Discriminant Analysis (LDA) was employed. The predictive performance of the LDA model was validated using Leave-One-Out (LOO) cross-validation. The following Python libraries were utilized: (1) Pandas (v1.3.5) and NumPy (v1.21.6) for data manipulation and numerical operations; (2) Scikit-learn (v1.0.2) for PCA, LDA, and cross-validation procedures; (3) SciPy (v1.7.3) for t-test calculations; (4) Matplotlib (v3.5.2) and Seaborn (v0.11.2) for the generation of high-resolution mirror plots, PCA score plots, and heatmaps.

RESULTS

To evaluate the proteolytic effects of pepsin on the human salivary proteome, whole saliva samples from ten healthy individuals were subjected to pepsin digestion under acidic conditions and analyzed using MALDI-ToF mass spectrometry. For each participant, one control sample and one digested aliquot were compared. Analysis of the acidified saliva samples provided a stable proteomic baseline. Following exposure to pepsin, distinct pepsin-induced proteomic changes were observed in the salivary samples. To assess the reproducibility of the digestion workflow, all pepsin-treated saliva samples were processed in technical duplicate. The duplicate digestions consistently produced comparable peptide profiles and signal intensities, confirming the robustness of the proteolytic procedure.

From the ten saliva samples analyzed, we identified three distinct salivary peptide profiles. Each profile combines a set of shared peptide signals with additional, profile-specific features that differ in intensity, even though the MALDI-ToF analytical conditions were kept constant. These reproducible patterns, observed across individuals, indicate inherent variability in the salivary peptide composition. Such variability is expected, as the salivary peptidome is influenced by physiological factors including individual protease activity, oral microbiota, hydration status, and subtle differences in sample handling. Consequently, the presence of distinct peptide profiles among healthy participants is consistent with previously reported inter-individual diversity in the human salivary proteome(14). Within these three categories, sample C1 displayed a peptide profile highly similar to that of sample C6, while the profile of sample C2 closely resembled that of sample C9. In contrast, samples C3-C5, C7, C8, and C10 formed a larger group characterized by markedly similar peptide patterns. This clustering further supports the presence of inherent inter-individual variability in salivary peptide composition under identical MAL-

DI-ToF analytical conditions.

To exemplify the three peptide profile types identified among the ten saliva samples, we present representative MALDI-ToF spectra corresponding to each category. Figure 2 illustrates the first profile type, using sample C1 as a representative example. Panel A shows the peptide mass fingerprint of the untreated saliva sample (C1), characterized by a series of well-defined signals spanning the 450-5000 m/z range, reflecting the endogenous salivary peptide distribution under acidic conditions. Panel B displays the corresponding spectrum of the same sample following pepsin digestion (D1), where shifts in peak intensities and the appearance of additional lower-molecular-weight ions indicate pepsin-mediated proteolysis. Figure 3 illustrates the second peptide profile type identified among the ten saliva samples, using sample C2 as a representative example. Panel A shows the MALDI-ToF spectrum of the untreated saliva sample C2, characterized by a distinct distribution of endogenous peptide signals that differentiates this profile from the one shown in figure 2. Panel B presents the corresponding spectrum of the same sample following pepsin digestion (D2). As observed for the first profile type, pepsin exposure results in the appearance of additional low-molecular-weight ions and modifications in peak intensities; however, the fragmentation pattern and relative signal distribution are characteristic of this second profile category.

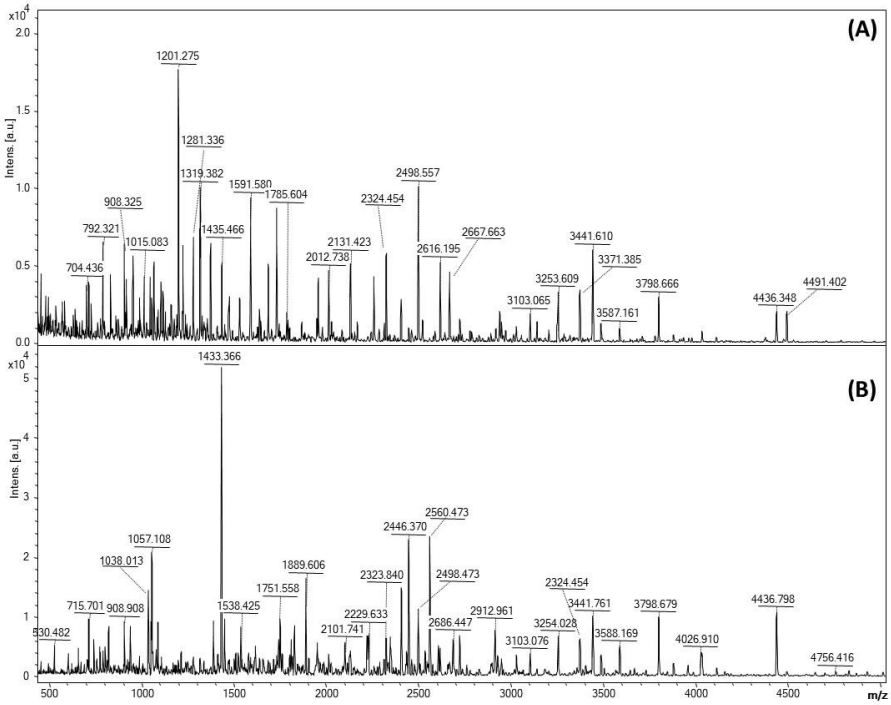

Fig. 2. Mass spectrometric peptide mass fingerprints illustrating one of the three salivary peptide profile types identified among the ten saliva samples. (A) MALDI-ToF spectrum of the untreated saliva sample C1 and (B) Corresponding MALDI-ToF spectrum of the same sample following pepsin digestion (D1)

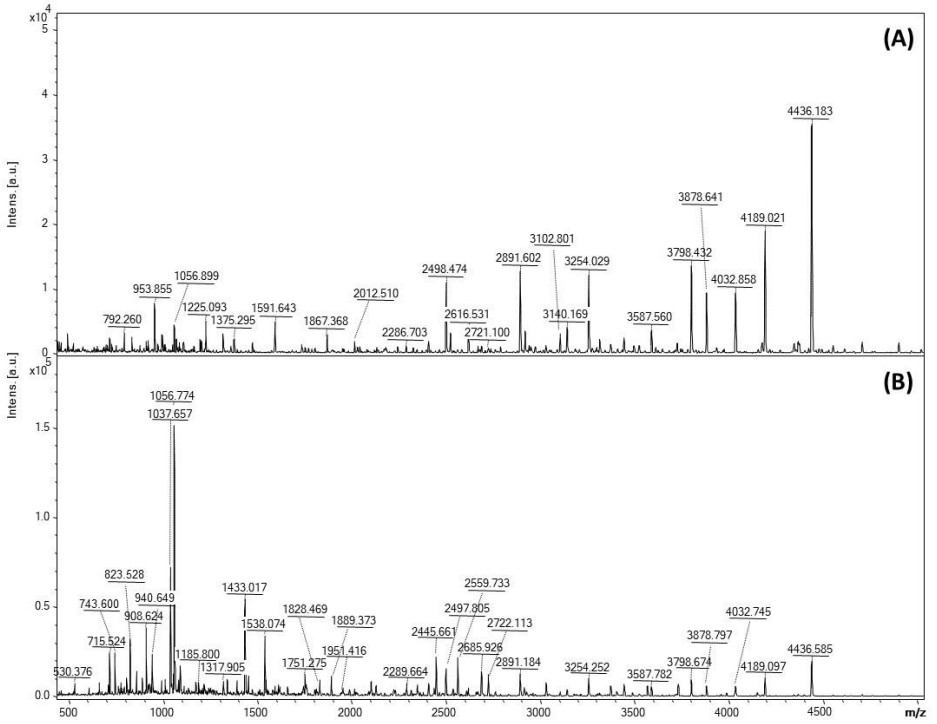

Fig. 3. Mass spectrometric peptide mass fingerprints illustrating a second salivary peptide profile type identified among the ten saliva samples. (A) MALDI-ToF spectrum of the untreated saliva sample C2, and (B) Corresponding MALDI-ToF spectrum of the same sample after pepsin digestion (D2).

Figure 4 illustrates the third peptide profile type identified among the ten saliva samples, using sample C7 as a representative example. Panel A shows the MALDI-ToF spectrum of the untreated saliva sample C7, characterized by a peptide distribution that is distinct from the patterns observed in figures 2 and 3. This profile type is defined by a specific arrangement of endogenous peptide signals and relative peak intensities that consistently grouped samples C3-C5, C7, C8, and C10 within the same category. Panel B presents the corresponding spectrum of the same sample following pepsin digestion (D7). As with the other profile types, pepsin exposure results in the appearance of additional low-molecular-weight ions and notable shifts in peak intensities. However, the fragmentation pattern observed for C7/D7 is characteristic of this third profile category and differs from the proteolytic signatures (figs. 2, 3).

For the in-silico component of the study, a dedicated salivary protein database was first constructed from the UniProt Knowledgebase (UniProtKB). A keyword search using the term “salivary” was performed and restricted to the organism Homo sapiens (Human). This query yielded 638 protein entries, which were exported and compiled into a custom

FASTA database for subsequent computational analysis.

In silico proteolysis was carried out using the MS-Digest online tool available through the Protein Prospector suite (https://prospector.ucsf.edu/prospector/cgi-bin/msform.cgi?form=msdigest).

Pepsin (porcine gastric) was selected as the proteolytic enzyme to replicate the experimental digestion conditions. Default digestion parameters were applied, including fully specific enzymatic cleavage according to pepsin specificity rules and allowance for up to two missed cleavages. No fixed or variable post-translational modifications were introduced, so the generated peptide list reflected cleavage based solely on primary amino acid sequence.

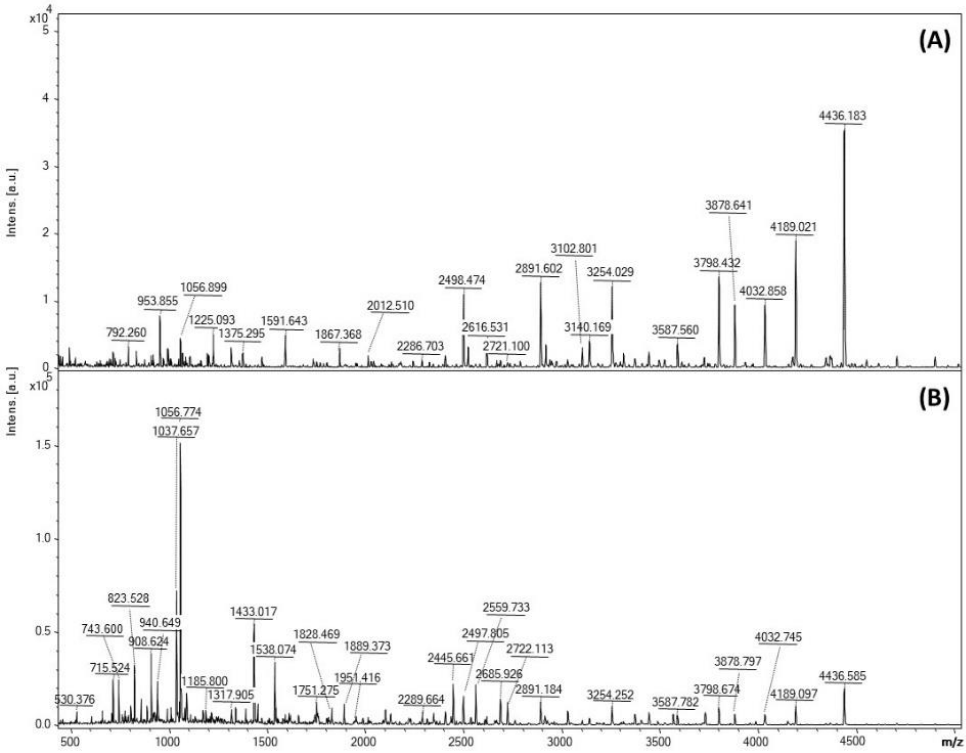

Fig. 4. Representative MALDI-ToF peptide mass fingerprints illustrating the third salivary peptide profile type identified among the ten saliva samples. (A) MALDI-ToF spectrum of the untreated saliva sample C7, and (B) Corresponding MALDI-ToF spectrum of the same sample following pepsin digestion (D7).

Application of these parameters to the 638 salivary protein entries resulted in 25009 theoretical peptide fragments. Because MALDI-MS analysis primarily provides peptide mass information without complete sequence coverage for all detected ions, the in-silico digestion served to generate a list of putative peptide sequences corresponding to experimentally observed m/z values (assuming a +1-ion charge). Therefore, fragment assignment was based on mass matching and represents

predicted candidate sequences rather than unequivocal sequence confirmation in all cases. This approach enabled a systematic comparison between experimentally detected pepsin-derived fragments and theoretically expected cleavage products within the human salivary proteome.

To further explore the variability observed across the salivary peptide profiles and to quantify the proteolytic effects of pepsin, all MALDI-ToF spectra from the control and digested samples were subjected to comprehensive statistical analysis. After peak alignment and intensity normalization, the dataset was evaluated using multiple multivariate approaches, including Principal Component Analysis (PCA), Linear Discriminant Analysis (LDA), and hierarchical clustering with heatmap visualization. These complementary methods enabled the identification of sample groupings, the discrimination between control and pepsin-digested spectra, and the detection of m/z features contributing most strongly to sample separation.

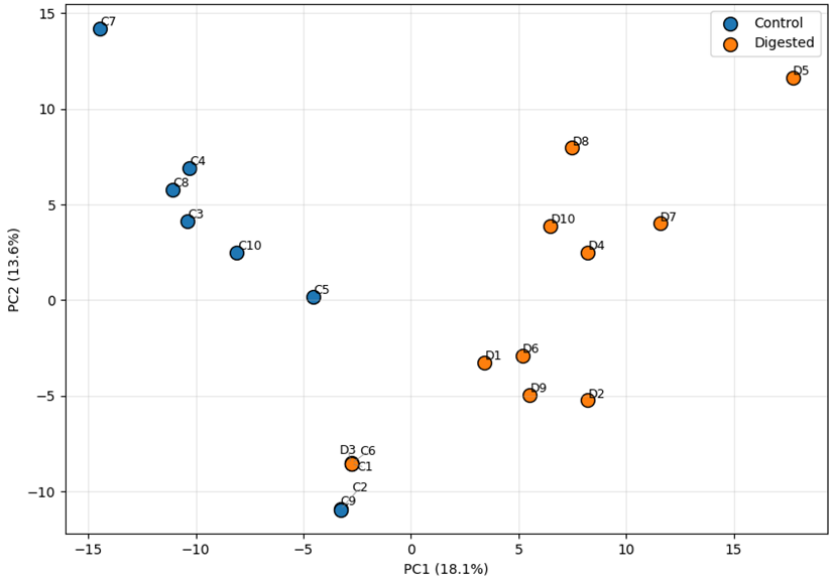

Fig. 5. PCA score plot illustrating the separation between control and pepsin-digested saliva samples (variance explained: 31.7%).

The PCA plot illustrates the impact of pepsin digestion on the salivary peptide composition (fig. 5) (15). The first principal component (PC1) captures the dominant source of variation in the dataset and clearly separates the digested samples (orange circles) from the native saliva samples (blue circles). This distinct clustering demonstrates that pepsin digestion consistently produces a characteristic peptide pattern that is markedly different from the natural inter-individual variability observed in untreated saliva. The separation along PC1 is driven by a specific subset of peptide ions whose intensities increase substantially following pepsin exposure. These ions correspond to the loadings of the first principal component and represent the features most

strongly contributing to the discrimination between the two sample groups.

TABLE I.

Top m/z ions ranked by their PC1 loading values, highlighting the peptide features most strongly associated with pepsin-induced spectral changes.

m/z (Ref)	PC1 Loading Value
530.34	+0.1076
743.49	+0.1075
940.5	+0.1074
1088.82	+0.1072
1750.99	+0.1070
1432.76	+0.1062
908.46	+0.1043
2289.27	+0.1036
1537.94	+0.0998
2406.36	+0.0992

In addition, hierarchical clustering of the most discriminative m/z features revealed a distinct grouping of ions that were consistently enriched in the pepsin-digested samples (tab. I). Based on the PCA loadings, the m/z features contributing most strongly to PC1 were ranked in descending order according to their loading values. The ions with the highest positive influence on PC1 were m/z 530.34, 743.49, 940.50, 1088.82, and 1750.99, followed by m/z 1432.76, 908.46, 2289.27, 1537.94, and 2406.36. Importantly, all top contributors exhibited positive loading values, indicating that their intensities increase systematically in the digested samples and drive the rightward shift of these samples along the PC1 axis. Notably, the peptide masses (tab. I) are also found among the theoretical peptides generated in the in-silico digestion, further supporting their biological relevance. These reproducible features may represent candidate biomarkers of pepsin - mediated proteolysis, pending confirmation through targeted MS/MS identification and validation in independent sample sets.

Building on the PCA findings and the discriminative m/z features (tab. I), the Linear Discriminant Analysis (LDA) provides a supervised dimensionality-reduction approach designed to identify the peptide signals that best separate the two predefined groups(16). Unlike PCA, which captures the directions of maximum variance without using class information, LDA explicitly incorporates the sample labels and learns the optimal combination of m/z features that distinguishes the Control from the Digested spectra (17). The resulting discriminant axis (LD1) positions most native saliva samples on the left and the pepsin-digested samples on the right, reflecting the consistent biochemical shift induced by proteolysis. The central red line represents the decision boundary used for classification. Two samples (C1 and D3) appear near this threshold, indicating intermediate peptide profiles that partially overlap with the opposite group, a finding consistent with the natural inter-individual variability of the salivary peptidome and with the PCA-derived loadings. Model performance was evaluated through Leave-One-Out cross-validation (LOO)(18), yielding an accuracy of 60%, further supporting the conclusion that pepsin digestion introduces systematic and detectable changes in the salivary peptide patterns (fig. 6).

To further extend the multivariate analysis and to visualize sample-level differences across the most relevant peptide markers, a heatmap with hierarchical clustering was generated using the top 15 m/z

features that most strongly distinguished the Control and Digested groups (fig. 7). These peptides ions correspond to the statistically significant markers identified in the PCA loadings and summarized in first table, and their intensity patterns provide a high-density over-view of the proteolytic changes induced by pepsin digestion.

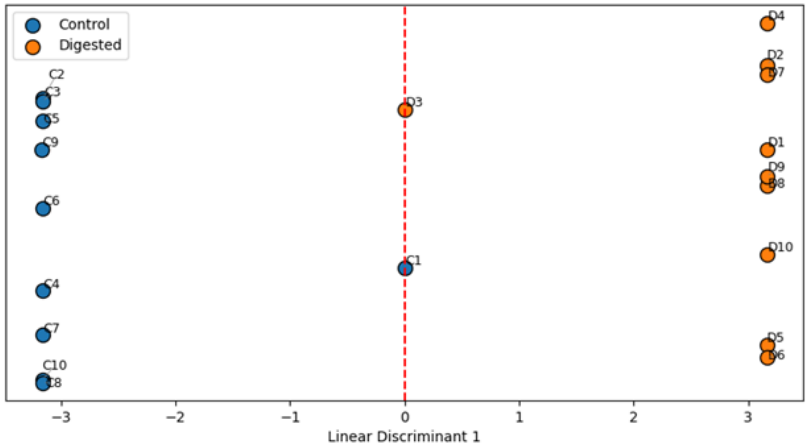

Fig. 6. Linear Discriminant Analysis (LDA) of control and pepsin-digested saliva samples, showing group separation along the LD1 axis and the decision boundary used for classification (LOO accuracy: 60%).

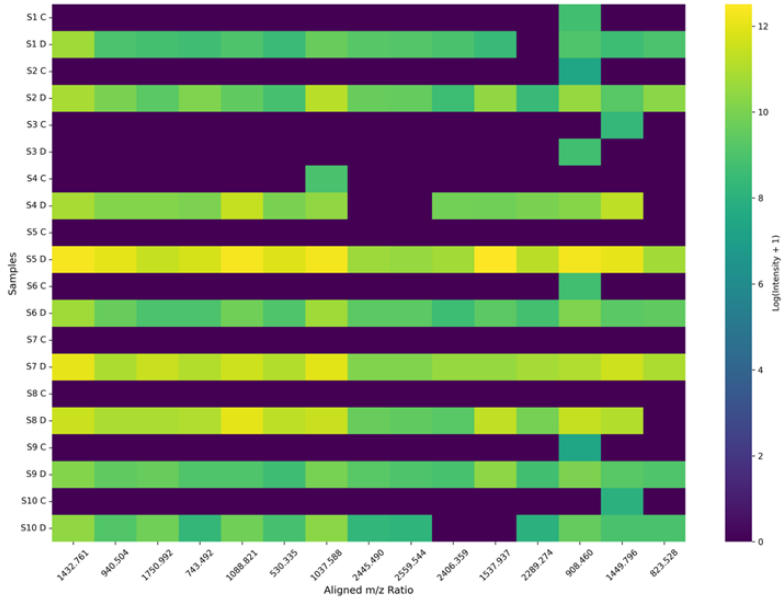

Fig. 7. Heatmap with hierarchical clustering of the top 15 discriminative m/z features, illustrating distinct intensity patterns between control and pepsin-digested saliva samples and highlighting sample-level variability across the dataset.

The heatmap reveals two clearly separated clusters, with control samples displaying consistently lower intensities for these m/z values, while digested samples exhibit marked increases, in agreement with the PCA and LDA results. Notably, Sample 3 shows an atypical pattern: although internally variable, it lacks several of the discriminative m/z features present in the other samples. This explains its divergent position in the clustering and reflects natural inter-individual variability rather than a computational artifact. Overall, the heatmap reinforces the biological relevance of the peptide markers enriched in the digested samples and supports their potential as candidate indicators of pepsin-mediated proteolysis, pending MS/MS validation.

DISCUSSION

GERD is one of the most prevalent gastroenterological disorders encountered in clinical practice, and there is a pressing need for non-invasive diagnostic tools to improve diagnostic accuracy. Saliva has emerged as an attractive and easily accessible diagnostic medium, capable of reflecting both systemic and local pathological processes (19, 20). Salivary pepsin has been investigated as a potential biomarker for GERD; however, reported sensitivity and specificity vary widely across studies, likely due to substantial methodological heterogeneity (21, 22). These limitations suggest that measuring pepsin concentration alone may not fully capture the complexity of reflux-related pathophysiology.

Pepsin is not merely a passive marker of reflux but an active proteolytic enzyme that remains biologically functional under acidic conditions and has been implicated in mucosal injury and inflammation in reflux disease (23, 24). Salivary proteins are more susceptible to proteolytic degradation than serum proteins (25, 26), making the salivary peptidome particularly responsive to pepsin-mediated cleavage.

Disease- or exposure-related alterations can reshape the proteome by generating distinct peptide patterns that reflect functional proteome states, rendering peptide-level analysis especially informative in dynamic biofluids such as saliva (27).

Recent advancements in proteomic technologies have expanded the potential of saliva as a diagnostic medium for a wide range of conditions, including head-and-neck and oral cancer, diabetes, gastric cancer, Sjögren's syndrome, primary sclerosing cholangitis, and COVID-19 infection (8, 28-30). As a proof-of-concept, this study employed MALDI-ToF mass spectrometry to characterize pepsin-induced alterations in the salivary peptidome of healthy volunteers, with the aim of identifying digestion-associated peptide patterns that may serve as indicators of reflux-related enzymatic activity. MALDI-ToF enables rapid and accurate analysis of complex biological samples by determining the mass-to-charge (m/z) ratios of ionized peptides based on their time-of-flight, making it a promising tool for medical diagnostics and biomarker discovery (31, 32).

Previous studies have shown that individuals with GERD exhibit lower oral pH values, which may influence the oral environment (33-35). Proteomic analyses of the acquired enamel pellicle in GERD patients have revealed profound alterations compared to controls, both in individuals with and without erosive tooth wear (36, 37). Moreover, clinical studies of saliva in GERD have demonstrated reflux-associated

remodeling of the salivary proteome, particularly affecting proteins involved in acid resistance and oral tissue protection (38). These findings collectively support the rationale for exploring pepsin-induced peptide signatures as potential biomarkers of reflux activity.

Our results demonstrate that pepsin induces marked and reproducible alterations in the salivary peptidome, reflected by both quantitative and qualitative changes across multiple analytical levels. MALDI-ToF profiling revealed a significant increase in the number of detectable peptide signals following enzymatic digestion, together with the appearance of novel m/z peaks absent in untreated saliva. These findings were further supported by multivariate statistical analyses. PCA showed a clear separation between native and digested samples along PC1, driven by a subset of peptide ions with strongly positive loading values, indicating systematic increases in their intensities after pepsin exposure. The most influential of these features are summarized in first table and overlap with peptides predicted through in silico digestion, reinforcing their biological plausibility.

LDA provided complementary evidence by identifying the optimal combination of discriminative m/z features that maximized group separation. Despite natural inter - individual variability, most samples were correctly classified, and the model achieved a 60% LOO accuracy. Samples positioned near the decision boundary (e.g., C1 and D3) displayed intermediate peptide profiles, consistent with the variability observed in the PCA and heatmap analyses. The hierarchical clustering heatmap of the top 15 discriminative m/z features further confirmed the presence of two distinct sample clusters, with digestion-specific peptides showing consistently elevated intensities in the digested group. One sample (Sample 3) exhibited an atypical pattern due to the absence of several discriminative m/z values, reflecting internal variability rather than analytical error. Together, these converging lines of evidence highlight robust pepsin-induced remodeling of the salivary peptidome. The reproducible detection of digestion-specific peptides across multiple individuals, combined with their statistical relevance and alignment with in silico predictions, supports their potential as candidate biomarkers of reflux-associated pepsin activity. As a proof-of-concept, this study demonstrates the feasibility of using salivary peptidomics to detect enzymatic signatures associated with gastric reflux.

To advance this line of research, we will perform high-resolution ESI-MS/MS analysis of the salivary samples to determine the precise amino-acid sequences and protein origins of the candidate biomarker peptides. This step is essential for confirming their biological relevance and for establishing mechanistic links between pepsin activity and specific proteolytic cleavage events. In parallel, we will expand the study to include clinical cohorts, particularly patients with confirmed GERD, as well as individuals with oral or upper gastrointestinal cancers and patients undergoing chemotherapy, in whom reflux is a frequent adverse effect. Such cohorts will allow us to evaluate whether the digestion-associated peptide signatures identified here are detectable in real-world pathological conditions and whether they correlate with disease severity, symptom burden, or treatment-related reflux.

By integrating controlled experimental data with clinical validation, future studies

will determine the diagnostic robustness, specificity, and translational potential of these salivary peptide markers. Ultimately, this research may contribute to the development of rapid, non-invasive, saliva-based diagnostic tools capable of complementing or reducing reliance on invasive procedures such as pH-monitoring or endoscopy.

CONCLUSIONS

This proof-of-concept study demonstrates that pepsin exposure under acidic conditions induces significant and reproducible alterations in the salivary peptidome, generating distinct peptide signatures that differentiate digested from native saliva. These findings provide foundational evidence supporting the feasibility of saliva-based, non-invasive diagnostics for reflux-associated enzymatic activity. However, several limitations of this proof-of-concept study should be considered. In particular, the human salivary proteome exhibits substantial proteome complexity, consisting of multiple proteoforms generated through proteolytic processing, post-translational modifications, and sequence variation. While MALDI-ToF peptide profiling enables rapid detection of digestion-associated peptide patterns, this approach does not resolve intact protein species and therefore cannot fully capture the diversity of proteoforms present in saliva. Consequently, the peptide signals reported here represent inferred fragments of the salivary proteome, and their identities remain putative until confirmed by tandem MS analysis. In addition, the relatively small sample size and the use of experimentally digested saliva from healthy volunteers limit the generalizability of the findings. Future studies will focus on structural identification of the candidate peptides through ESI-MS/MS and on validating these biomarkers in clinical cohorts, including patients with GERD and individuals with reflux-related symptoms secondary to oncologic therapies.

CONFLICTS OF INTEREST AND FUNDING

The authors declare no conflicts of interest.

This research received no external funding. Brîndușa Alina Petre gratefully acknowledges the support received, in 2025, through the Fulbright Visiting Scholars Program, awarded by the Romania-USA Fulbright Commission, for her fellowship at Clarkson University, Potsdam, NY, USA.

EPIDEMIOLOGICAL ASPECTS OF TUBERCULOSIS IN EAST ROMANIA (Abstract): Tuberculosis continues to represent an extremely major problem of public health worldwide, with global economic and social implications. **Aim** of the study was to evaluate some variables in children admitted with *Mycobacterium tuberculosis* infections. **Material and methods**: The descriptive study performed on a group of 1,849 patients aged between 0-18 years, during 2010 and 2014. **Results**: Distribution of cases highlighted that pediatric patients were more frequently girls (M/F = 0.97), from urban areas (U/R= 1.29), aged of 10-14 (33.04% of total cases), then 5-9 (28.18%). Children of 0-4 age group represented 17.18% of total cases. **Conclusions**: The present study represented the second part of a larger surveillance study started in 1999, with first results published in 2007. The study will be continued next years, taking into consideration also other variables with clinical importance in pediatric patients. **Keywords**: TUBERCULOSIS, CHILDREN, EPIDEMIOLOGY, PNEUMOLOGY.

It is estimated that one-third of the globe population is infected with *Mycobacterium tuberculosis*, and over 10 million cases of tuberculosis (TB) occur every year. Although the disease is curable, there are millions of deaths annually. TB is one of the most important causes of death due to a microorganism and considering the causes of avoidable death, the most important cause of death in the adult population group and an important burden at childhood age. TB continues to represent an extremely major problem of public health worldwide, with global economic and social implications, because over 80% of total deaths occur in active social and demographical age group people of 15-59 years old. TB was considered too one of the main causes of DALY worldwide, after lower respiratory tract infections, diarrheal diseases, perinatal disorders, major unipolar depression, ischemic heart disease and

cerebrovascular accidents). In 2020, it is estimated that there will be a reversal of disease on this scale, meaning that ischemic heart disease will be on the first place, major unipolar depressions on second, road accidents on third, but TB will be on the spot. Another major problem involving TB is the drug-resistant cases. In 2016, 600,000 new cases resistant to rifampicin, the most effective first-line drug, were reported, according to Global tuberculosis report published by WHO experts. The multidrug-resistance was reported for 490,000 cases (MDR-TB) and 47% of these cases were in India, China and the Russian Federation (1, 2, 3, 4, 5).

Specific TB reporting indicators are well defined at the global and national level. Since 1995 standardized TB cases and treatment outcomes have been reported, with incidence and mortality estimates published. WHO has developed a TB-MDR monitoring program with 14 indicators, including the state of well-being and health of the individual, coverage of essential health services, per capita health expenditure, and smoking, diabetes, alcohol consumption. Other indicators are related to the proportion of the population living below the poverty level, the proportion of the health insurance population, the social protection systems, the prevalence of malnutrition, the gross domestic product, etc. To these, the WHO adds the Gini index to income inequality and the proportion of urban population but living in poverty (1, 2, 3).

The implications of TB infection should be analyzed by looking at some specific examples of TB evolution at global and regional level. A first example is the situation in Romania where the measures taken in a certain period led to the decrease of the incidence of TB to 56%ooo in 1985, the incidence in 2000 being more than twice as high. A second example relates to the evolution of TB in the US, where the target for elimination was established by 2010 but cannot be achieved. Due to an erroneous interpretation of the global situation in the 1970s, the attitude towards MT in the US has changed dramatically. In this context, the continued incidence of TB during the period 1985-1992 (with 26,673 cases reported in 1992) was possible, mainly due to: the deterioration of public health infrastructure (especially in the field of infectious diseases and in particular TB) (after 1972), the emergence of the HIV/AIDS epidemic, the reduction of TB training, the decrease of research activities, immigration from endemic countries, the reduction of social programs, transmission of infection in certain units (hospitals, hostels, prisons, etc.) the emergence of infections with resistant and multi-resistant strains of *M. tuberculosis*. The "American" model is very suggestive and can be extrapolated to what has happened in other industrialized countries over the same period and the above-mentioned causes must be considered when developing an effective TB prevention and control strategy (1, 2, 5).

The present study represented the second part of a larger surveillance study started in 1999, with first results published in 2007 (6). The same specific aim was considered to identify and describe demographic variables with clinical and epidemiological importance in pediatric patients with *M. tuberculosis* infections.

MATERIAL AND METHODS

The study was performed between 2010 and 2014 on group of 1,849 patients admitted to a Clinical Emergency Hospital for Children in Galati County, a region situated

in the Eastern part of Romania.

Mycobacterium tuberculosis evidence in their pathological isolates was mandatory. The inclusion criteria were pediatric age groups and the presence of *M. tuberculosis* in pathological isolates. The exclusion criteria did not involve residence area, nor gender or other comorbidities. Data were collected from patients' recordings and hospital statistical reports, and processed using *MS Excel* 2010.

RESULTS

Distribution by year of study described an increased trend from 2010 to 2014 in incidence of *M. tuberculosis* isolates, with a minimum value during 2012 (344 cases) and a maximum in 2014 (399 cases). Calculated average = 369.8; median - 373.6. (fig. 1).

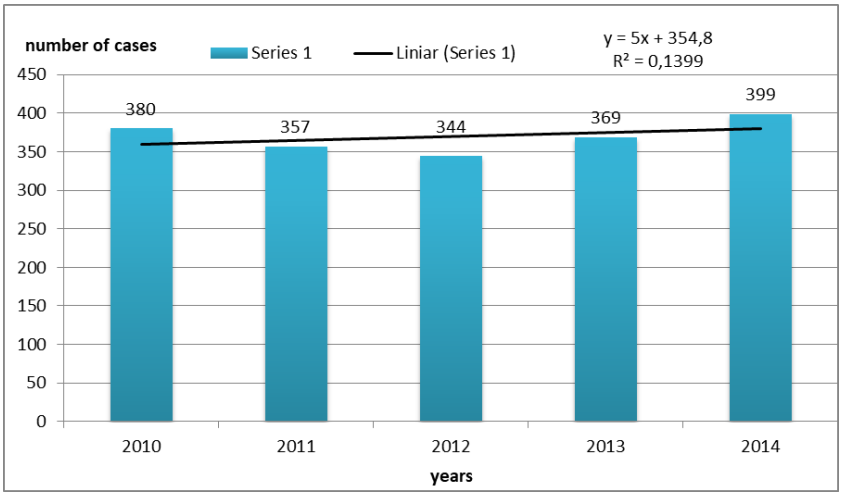

Fig. 1. Distribution of cases by year of study

Distribution by gender showed that girls were more frequent diagnosed with a *M. tuberculosis* infection than boys, with a total M/F = 0.97, but with no statistical significant difference in male / female in every year of study (tab. I).

TABLE I

Distribution of cases by gender

Year of study	Distribution by gender				Total
	Female		Male		
	No.	%	No.	%	
2010	188	49.47	192	50.53	380
2011	184	51.54	173	48.46	357
2012	159	46.22	185	53.78	344
2013	192	52.03	177	47.97	369
2014	213	53.38	186	46,62	399
Total	**936**	**50.62**	**913**	**49,38**	**1849**

The next demographic variable considered was the residence area, showing there was a statistical significant difference between urban and rural patients in 2011 and 2012 ($p<0.05$) and with U/R = 1.29 (tab. II).

TABLE II
Distribution of cases by residence area

Year of study	Distribution by area				Total
	Urban		Rural		
	No.	%	No.	%	
2010	215	56.57	165	43.43	380
2011	221	61.91	136	38.09	357
2012	212	61.62	132	38.38	344
2013	187	50.68	182	49.32	369
2014	208	52.13	191	47.87	399
Total	**1043**	**56.41**	**806**	**43.59**	**1849**

Calculated trends during the studied years highlighted that female cases had an up-trend, but patients from urban area a down trend (fig. 2).

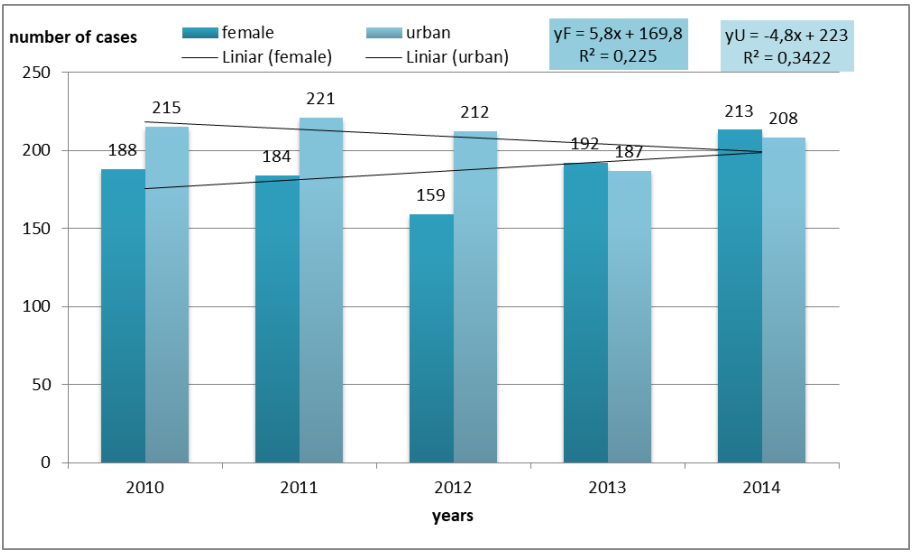

Fig. 2. Comparative distribution of cases by the most frequent gender and area variables

Pediatric age group distribution showed that children studied group aged of 10-14 years were the most frequently affected by infections with *M. tuberculosis*, with a total of 611 cases or 33.04%, followed by 5-9 aged patients (521 cases meaning 28.18% of total).

Children aged between 0 and 4 years represented only 17.19% of cases, but with an important clinical and epidemiological significance (tab III, fig. 3).

TABLE III

Distribution of cases by age group

Year of study	Distribution by age group (years)								Total
	0-4		5-9		10-14		15-18		
	No.	%	No.	%	No.	%	No.	%	
2010	92	28.93	112	21.49	89	14.56	87	21.81	380
2011	52	16.35	87	16.69	154	25.21	64	16.04	357
2012	38	11.95	84	16.12	151	24.71	71	17.79	344
2013	63	19.81	134	25.72	93	15.21	79	19.79	369
2014	73	22.96	104	19.98	124	20.31	98	24.57	399
Total	**318**	**17.19**	**521**	**28.18**	**611**	**33.04**	**399**	**21.59**	**1849**

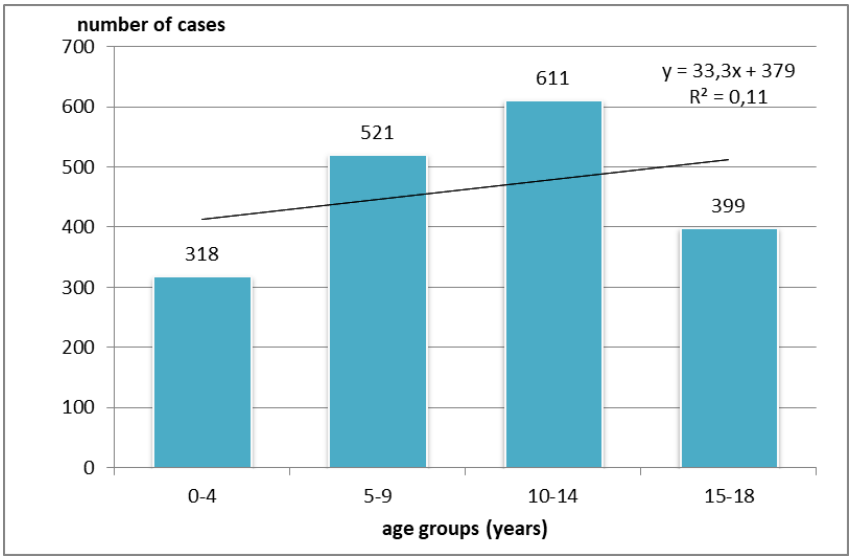

Fig. 3. Age histogram

DISCUSSION

Tuberculosis accounts for more than 20% of all TB cases in countries with high incidence of the disease and 5% in high developed regions. TB in children is a neglected pathology that remains in the adult shadow because of negative smears often detected so that the burden of this disease in pediatric age is underreported. WHO highlighted that positive TB in children under the age of 14 represented 0.6-3.6% of total cases. Most of children under 12 could have negative smears. Countries with high rates of TB rarely performed specific smears in children. Children with TB are often the result of contamination from adult sources. Infants are at risk of serious clinical forms because of immune system immaturity. Nonspecific clinical and radiological signs and variability of them in children are sometimes ignored and make the diagnosis diffuse and imprecise. Treatment can involve multidrug resistant strains, resulting in a reserved prognosis. All these

obstacles, including an increased prevalence of HIV co-infection, require the development of an effective anti-TB vaccine and immunosuppressed patients and a better knowledge of epidemiological features in these age groups (7, 8, 9, 10).

TB has an unequal distribution in all populations, affecting risk groups and being considered a disease of "poverty". Favoring and aggravating factors would be malnutrition, poor living conditions, low income and unemployment, limited access to healthcare services, unfavorable psychosocial influences may affect patients and their families. These population groups at risk have a higher prevalence of TB that often remains undiagnosed for a long time and thus individuals become unknown sources of pathogen for the entire community. Delay in diagnosis due to all the above-mentioned factors leads to aggravation of symptomatology. These patients difficult adhere to treatment and therefore therapy has unfavorable results. Such groups are extremely fragile and must be identified as early as possible to implement properly the management of global control of communicable diseases in populations in which social factors, with the marginalization of these individuals, play an important role (11, 12, 13).

The WHO Millennium goal of eliminating TB by 2050 requires both healthcare and population efforts to improve cooperation on hospital admission and therapy compliance. However, there are several obstacles that seem to impede the achievement of this goal, such as the still high prevalence of TB. Increasing numbers of injecting-drug users in countries with numerous populations and at-risk groups such as India and China, the co-infection with HIV, are difficult to solve and require high costs (14).

CONCLUSIONS

Our descriptive study had its importance in assessing the incidence of *M. tuberculosis* infections in children, and highlighting certain demographic variables up-trended or down-trended during a half-decade. The study will be continued next years, taking into consideration other variables, with clinical importance in pediatric patients.

NEWS

EVALUATION OF SERUM C-REACTIVE PROTEIN LEVELS IN SUBJECTS WITH AGGRESSIVE AND CHRONIC PERIODONTITIS IN COMPARISON WITH HEALTHY CONTROLS

The aim of a study realized by a group of Indian researchers was to evaluate and to compare the serum C-reactive protein levels in subjects diagnosed with chronic periodontitis and aggressive periodontitis. Forty-five subjects were included in the study. The subjects were divided into three groups: *group I* (subjects with clinically healthy periodontium), *group II* (subjects with generalized aggressive periodontitis), and *group III* (subjects with chronic periodontitis). For the measurement of serum C-reactive protein, blood samples were collected from all subjects. Periodontal parameters (plaque index, bleeding index, gingival index, probing pocket depth, clinical attachment loss) were assessed. Serum C-reactive protein levels were assessed by means of a commercially available high sensitivity- serum C-reactive protein enzyme immunoassay kit. The results showed that serum C-reactive protein levels were increased in group III (6.0671 ± 3.15639 mg/L) and group II subjects (4.5453 ± 2.88116 mg/L) compared to the group I (1.0180 ± 0.94069 mg/L). Serum C-reactive protein levels showed a positive correlation with all clinical parameters in group I subjects. Bleeding index (r = 0.073), plaque index (r = 0.120) showed a positive correlation with serum C-reactive protein level in group II and a positive correlation was also seen for plaque index (r = 0.492), probing pocket depth (r = 0.340), clinical attachment loss (r = 0.160), and serum C-reactive protein level in group III subjects. In conclusion, the mean serum C-reactive protein levels were found to be greater in patients with chronic periodontitis compared to those with generalized aggressive periodontitis, but there was no statistically significant difference. SINGLE LARGE SACCULATED DUODENOJEJUNAL FLEXURE DIVERTICULUM. CASE REPORT AND CLINICAL IMPACT (Abstract): A diverticulum can develop in any portion of the intestine. Jejunal diverticulum is a rare congenital malformation and refers to the presence of a sac-like mucosal herniation through vulnerable points of the intestinal wall. We herein report a case of an unusual finding of a single giant sacculated jejunal diverticulum located at the first part of the jejunum just after the duodenojejunal flexure in a cadaver. Diverticula usually remain entirely asymptomatic and commonly present with bloating and nonspecific symptoms. In many cases diagnosis is incidentally reached during surgery, endoscopy or imaging study for other reason. However, serious complications may develop, such as bowel obstruction and acute perforation, diverticulitis, bleeding, volvulus, anemia, malabsorption. Related clinical and surgical implications are discussed as well. Knowledge and familiarity with this rare entity is valuable to gastroenterologists when assessing abdominal symptoms and general surgeons, as well, when performing exploratory laparotomy. Although jejunal diverticular disease is a rare condition, potential complications could be fatal. **Keywords:** JEJUNUM, DIVERTICULUM, DIVERTICULITIS.

Jejunal diverticula (JD) constitute a rare entity of the small-bowel with a reported incidence of 0.5 to 2.3% (1) in enteroclysis studies, and a varying incidence of 0.26 (2) to 4.6% (3) in autopsy studies, predominantly affecting male gender (4). Gastroenterologists and colorectal surgeons should be familiar with this entity because they may deal with it in many different clinical settings, as a JD could be the incidental finding during the pre-operative work-up of a colorectal disease patient or radiographically discovered during diagnostic abdominal imaging studies. Intraoperatively, JD may become evident on routine abdominal exploration, or could be the cause of an acute abdomen (5). Some acute presentations of that jejunal malformation include hemorrhage, anemia, malabsorption, volvulus, intussusception, perforation, small-bowel obstruction (1).

We herein report a case of an unusually large, single diverticulum of the first part of the jejunum, just after the duodenojejunal flexure near the ligament of Trietz. Solid understanding of the underlying anatomy is fundamental to offer the best possible treatment to patients suffering from these lesions.

CASE PRESENTATION

During the routine dissection course for teaching and research purposes in the Department of Anatomy of Aristotle University of Thessaloniki, in the small-bowel of a formalin-alcohol fixed and embalmed 72-year-old Greek male cadaver we came across an unusual finding of a single giant JD adjacent to the ligament of Treitz arising from the mesenteric border and extending into the posterior wall of the jejunum. The JD displayed a broad base with a diameter of 4.85 cm and sacculated outer surface (fig. 1A) Precise shape and dimensions of that anatomical finding were determined after the inflation of the gut's lumen with water through a catheter placed at the fourth part of the duodenum, just proximal to the diverticulum. No abdominal symptoms or diseases were retrieved from the medical records of the body donor (fig. 2B). No other diverticula or a Meckel's diverticulum were found after a careful investigation of the rest of the bowel. The diverticulum was found at the initial portion of the jejunum just distal to Treitz ligament. The cause of death was unrelated to the current study. An uneventful cholecystectomy was performed 18 years ago because of an acute cholecystitis. No other concomitant anatomical variations in the abdomen existed. For documentation purposes, repeated photographs of this rare finding were taken.

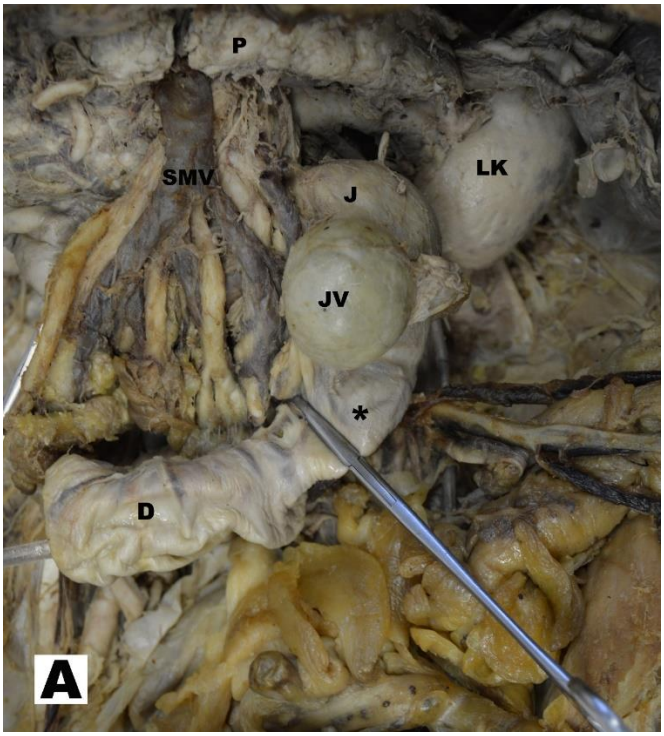

Fig. 1. A. The abdominal organs and vessels of the retroperitoneal space are demonstrated along with the first portion of the jejunum (J), where at the site of the duodenojejunal flexure (asterisk), a jejunal diverticulum (JV) is seen. The fourth portion of the duodenum (D) has been retracted distally. (P: pancreas, LK: left kidney, SMV: superior mesenteric vein).

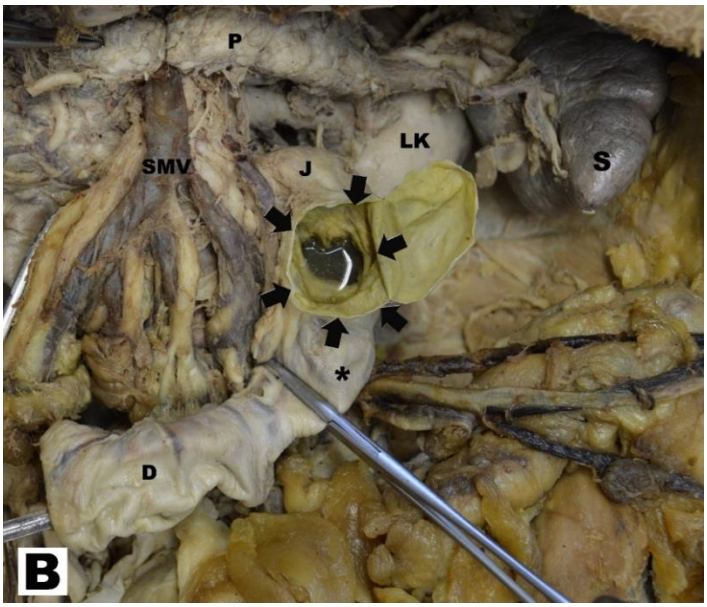

Fig. 1. B. The posterior wall of the jejunal diverticulum has been opened (arrows) to expose its lumen.

DISCUSSION

Although Sir Asley Cooper in 1807 mentioned the presence of JD in his treatise *"The anatomy and surgical treatment of crural and umbilical hernia"* (6), historically the first description of small-bowel diverticula (SBD) in autopsy studies is attributed to Sommering and Baillie in 1794 (7). The first clinical observation, however, was reported by Osler in 1881 (8), whereas the first operation for small-bowel diverticula was undertaken in 1906 by Gordinier and Sampson (9).

The incidence of JD on autopsy studies ranges from 0.26% to 4.6% (10). Noer inflated the small bowel with water, in a large autopsy series and concluded that SBV are more commonly located in the jejunum than in the ileum with an incidence of 8.3%, where twice as many men as women were found affected. In view of the nature of the diverticular wall the perforation cases are surprising low, and should be attributed to the considerable compliance of the submucosa which prevents rupture of the intestinal wall (3). About their precise location, they are most frequent at the proximal jejunum (75%), followed by the distal jejunum (20%) and the ileum (5%) (11). SBV to be more and larger in the proximal jejunum and fewer caudally (12). SBD may co-exist with diverticula of esophagus, stomach, duodenum, colon and urinary bladder, in most cases with that of the colon (11). Benson et al found that 57.65% of their patients with jejunal or ileal diverticula had also diverticula elsewhere in the alimentary tract, mainly in the colon (30 over 85%) (13). SBD are more common in males (13, 14). SBD are usually multiple, as many as 400 reported in one patient (15) SBD are rare congenital malformations of the intestine in children and young adults, most commonly diagnosed over the sixth decade of life, while various other alimentary tract diseas-

es, such as peptic ulcer, cholelithiasis and hiatal hernia may co-exist (13,14).

Non Meckelian SBD are pseudodiverticula, since they are outpouchings containing mucosa and submucosa only. Although etiology remains uncertain it is widely accepted that they develop as a result from high intraluminal pressure, through the muscular layer of the bowel at sites of low resistance, which are usually the points where blood vessels enter the bowel wall. Interestingly, another theory suggests that SBD are the product of intestinal dyskinesia, caused by smooth muscle discoordination (16) or abnormal peristalsis (17).

JD are rare congenital malformations of the small-bowel and most patients are asymptomatic, being the underlying cause of non-specific abdominal symptoms.

Even though clear majority of JD remain clinically silent, 20%- 30% of patients become symptomatic (1, 18). When symptoms become evident they may initially include mild epigastric pain, flatulence and malabsorption. Most commonly encountered acute complications involve inflammation, hemorrhage, perforation, abscess formation and intestinal obstruction (1, 19). Focusing on the location, SBD are statistically more prone to develop acute complications than duodenal ones (17). JD are nearly four times more likely to develop complications compared to duodenal diverticula and nearly 18 times more likely to perforate and develop abscesses (20).

Since most cases of JD remain asymptomatic or appear with vague symptoms, consequently diagnosis is usually delayed. On top of it no reliable diagnostic tests exist for this entity. The diagnosis is made incidentally either by radiographic examination or by laparotomy undertaken for complications (21). Diagnostic methods involved in JD diagnosis include abdominal radiographs where free air in the abdominal cavity may become evident. Computed tomography may reveal an abscess formation or pneumoperitoneum, while barium enema may show the corkscrew sign (22). The triad of obscure pain, anemia and dilated loops of small-bowel on barium radiographs is suggestive of JD presence (23). Diagnostic laparoscopy is very useful in investigating patients with a complicated symptomatology, avoiding, thus, an unnecessary laparotomy. In complicated cases of JD resection of the diseased bowel and a primary end to end anastomosis is required (5). In asymptomatic patients in whom the JD observed incidentally on computed tomography or intraoperatively, no action needs to be taken (24).

CONCLUSIONS

Since most cases of JD remain asymptomatic, general surgeons, gastroenterologists and other physicians involved in the abdominal pain assessment, should be aware and include it in their differential diagnosis. Jejunal diverticular disease may present with non-specific intermittent abdominal symptoms or rarely as acute abdomen with complicated symptomatology which may be fatal, unless prompt diagnosis is made and the appropriate surgical repair is offered to the patient.

MANAGEMENT OF DYSLIPIDEMIA IN CHILDHOOD MAY PREVENT CARDIOVASCULAR EVENTS IN ADULTS (Abstract): Risk factors that accelerate the atherosclerosis development are met since childhood and there are growing evidences which states that reducing them leads to a delay in clinical progression. The presence of cardiovascular risk factors, such as dyslipidemia at an early age, is associated with the presence of cardiovascular disease in adulthood. The ability to identify risk factors in children leads to an opportunity to prevent future cardiovascular events through an effective management of genetic and acquired risk factors. Incidence and prevalence of dyslipidemia among the children and teenagers are increasing from day to day. Identifying children with dyslipidemia, a high risk for an early and accelerated atherosclerosis, must include an extensive assessment of serum lipids and lipoproteins. The screening for dyslipidemia involves family history of hypercholesterolemia, cardiovascular incidents associated with dyslipidemia in relatives of first or second degree and elevated lipid profile for at least two determinations in children 2 to 8 years old and adolescents aged 12 to 16 years. Therapeutic intervention depends primarily on age. Initial approach will always include changes in diet and lifestyle. When necessary, drug treatment will be used in accordance with the recommendations for the different groups of ages. **Keywords:** DYSLIPIDEMIA, CARDIOVASCULAR RISK FACTORS, CHILDHOOD.

Dyslipidemia is associated with significant comorbidities, such as obesity, type 2 diabetes mellitus (DM) and essential hypertension (HBP). Obesity and diabetes are increasing among children and teenagers. Cardiovascular diseases are among the leading causes of death in developed countries and in Romania. Primary prevention aims to extend the range of time from identifying cardiovascular risk factors and cardiovascular disease expression (1).

It is well known that serum levels of lipids and lipoproteins vary depending on age, gender and race, normal values in children under 19 years being different compared to those of adults (2, 3). In childhood, the predominant pattern of dyslipidemia is combined, they can associate moderate to severe elevated values of triglycerides (TG), normal to slightly increased values of LDL- cholesterol (LDL-c) and reduced values of HDL-cholesterol

(HDL-c). Both patterns of dyslipidemia have been shown to be associated with the onset and progression of atherosclerotic lesions in children (4).

It has been found that during puberty lipid levels are lower (total and LDL-cholesterol levels can be reduced by 10% to 20% or more), and after this period, they increase again. Also, after the onset of puberty, increased values of total and LDL-cholesterol was found in girls (3).

Generally, there are four classes of dyslipidemia in pediatric patients known as: medication-related dyslipidemia, dyslipidemia caused by lifestyle factors, genetic dyslipidemia and dyslipidemia secondary to other diseases. Also, there have been described 3 types of genetic dyslipidemias:

- familial hypercholesterolemia is an autosomal dominant disorder caused by severe elevations in total cholesterol and LDLc.
- familial combined hyperlipidemia caused by high LDL-C and triglycerides (TG) levels.
- familial severe hypertriglyceridemia caused by severe hypertriglyceridemia (>885 mg/dL) (5).

The screening of dyslipidemia

The age of 10 (age range 9-11 years) is an ideal time for screening all children (universal screening) (4). The screening is based on a standard lipid panel, taken after fasting, that includes total cholesterol, triglycerides, HDL and LDL-cholesterol. If the child is not fasting it will be investigated non-HDL-c (calculated as: Total Cholesterol - HDL-c) is recommended in the initial screening (which is not influenced by food or drink), unlike triglycerides or LDL-c. Calculated LDL-c is based to the Friedewald formula: Total Cholesterol - triglycerides / 5 + HDL-c (which are influenced by food or drink). Significant increased triglyceride (e.g.>400 mg/dL) excludes LDL-c calculation rule using the Friedewald equation (commonly used by most laboratories). If non-HDL-c is increased (> 145 mg/dL), will have to obtain two lipids profiles *a jèun* for 3 months, with at least 3 months break between assessments (2, 6).

According to the Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents 2011 the screening of dyslipidemia is recommended in the following cases:

- children aged over 2 years old with a family history of hypercholesterolemia - one or both parents with total cholesterol ≥ 240 mg/dL or with known dyslipidemia;
- children aged 2 to 8 years and adolescents aged 12 and 16 years, with two modified lipid profiles (every 2 weeks and repeated at 3 months) to detect risk factors;
- in the presence of cardiovascular risk factors;
- in the presence of a significant cardiovascular family history: parents/grandparents, < 55 years for men/< 65 years for women, who have suffered an acute myocardial infarction or sudden death, with atherosclerotic coronary disease, cerebrovascular or peripheral vascular disease;
- universal screening in children aged between 9 and 11 years (before the onset of puberty) with/without cardiovascular risk factors, repeated after the age of 17 years (4).

The results of screening are considered significant if LDL-c is higher than 130 mg/dL, non-HDL-c > 145 mg/dL, HDL c < 40 mg/dL and TG > 100 mg/dL (children under 10 years) or 130 mg/dL (children over 10 years); lipidic profile must be repeated over 14 days (6) (tab. I).

TABLE I

Plasmatic distribution of lipids in children and teenagers

	Normal	Borderline	High
Total cholesterol	< 170 mg/dL	170−199 mg/dL	≥ 200 mg/dL
LDL- cholesterol	< 110 mg/dL	110−129 mg/dL	≥130 mg/dL
TG	0−9 yrs. <75 mg/dL 10−19 yrs. < 90 mg/dL	75−99 mg/dL 90−129 mg/dL	≥100 mg/dL ≥130 mg/dL
HDL- cholesterol	> 45 mg/dL	40−45 mg/dL	< 40 mg/dL
ApoB	< 90 mg/dL	90-109 mg/dL	> 110 mg/dL
ApoA1	>120 mg/dL	115-120 mg/dL	< 115 mg/dL

Cardiovascular risk factors and other causes of dyslipidemia

When cardiovascular risk factors are present at a younger age, their persistence into adulthood was associated with an increased risk for future cardiovascular disease. Identifying vulnerable populations allows the early prevention of CV risk factors progression and future cardiovascular events, with an effective management of genetic and acquired risk factors (7) (tab. II).

TABLE II

Criteria for cardiovascular risk factors and associated diseases

Criteria	Moderate risk	Increased risk
IMC	> 95 percentile but < 97 percentile	> 97 percentiles
Hypertension	HTA without treatment	HTA with treatment
HDL-c	< 40mg/dL	-
Smoking		Active smoker
Diseases	- Kawasaki disease with coronary aneurysms regression - Chronic inflammatory diseases (LES, juvenile inflammatory arthritis) - Nephrotic syndrome	- Kawasaki disease with coronary aneurysms progressive - type 1 and 2 diabetes - Chronic kidney disease/end-stage renal impairment/ post renal transplant status

Other causes of dyslipidemia should also be considered and evaluation should include a complete metabolic panel (liver tests, kidney tests, electrolytes) and specific tests according to secondary causes of dyslipidemia (6, 8) (tab. III).

TABLE III

Screening tests for others causes of dyslipidemia

Disease	Screening tests
Liver damage	Complete metabolic panel
Renal impairment	Complete metabolic panel, urine analysis
Hypothyroidism	TSH, FT4
Diabetes	Complete metabolic panel, urine analysis, postprandial glucose, HbA1c
Obesity / Insulin resistance	Complete metabolic panel, postprandial glucose, insulin
Medication	Steroids, contraceptives, retinoids, protease inhibitors

Management of dyslipidemia

The goal of dyslipidemia treatment is to maintain LDL-c < 30mg/dL, TG <150 mg/dL and HDL-c>35 mg/dL. Lifestyle improvement is the cornerstone of dyslipidemia management. Starting pharmacotherapy is recommended only in case of high or very high cardiovascular risk or if lifestyle changes do not improve lipid levels. The main classes of drugs are statins and omega-3 fatty acids (9).

Nutritional recommendations

Nutritional recommendations during the first 2 years of life

Natural feeding should be encouraged in all infants for the first 6 to 12 months of life. Subsequently, complementary feeding will be progressively introduced after the first 6 months of life. Lipid intake in children under 1 year of age should not be restricted without medical indication and for children over 1 year low saturated fat diet is recommended. It is indicated to avoid sweet juices and to limit the undiluted fruit juice to 100 mL/day. The child will be encouraged to drink water, eat fruits and vegetables, cereals and limit the salt intake. Lipid intake cannot represent more than 30% of the daily ration (saturated fat 8-10% of caloric intake, mono-unsaturated and poly-unsaturated 20% of the total fat intake) and avoiding trans-unsaturated fatty acids (6, 9).

Nutritional recommendations after the age of 2-years-old

It is recommended the consumption of low (2%) or without fat milk. Encourage children to drink water and avoid beverages with added sugar. The total content of fats in the diet of children with dyslipidemia should be 25% to 30%, with saturated fat lower than 10%, mono- and poly-unsaturated fat up to 20%, while avoiding the saturated and trans-unsaturated fatty acids as much as possible. The other 70% calories in the diet should be 15-20% from proteins and 50-55% from carbs. Portions must agree with the caloric intake recommendation for age and sex. Fiber intake is recommended (5 g + age in years/day; in adolescents - 14 g/1000 kcal) and salt intake should be limited. For children with hypercholesterolemia and high LDL-c it's recommended a saturated fat restricted diet (to ensure less than 7% of calorie needs) and limited dietary cholesterol to 200mg /day, with trans fats less than 1%. In high TG levels, the recommendations include the reducing of simple carbohydrates intake, associated with increased consumption of complex carbohydrates, lowering fat intake. If obesity is associated with increased TG. it is recommended to reduce caloric intake and increase the physical activity (6, 10, 11).

Physical activity and lifestyle

Physical activity has a beneficial effect on the children health. Like dietary choices, physical activity patterns are established in childhood and perpetuated further in adulthood. Therefore, the family is primarily responsible for encouraging children to adopt a healthy lifestyle. Physical activity is associated with lower blood pressure, body fat reduction, decreased BMI, decreased TC, LDL-c and TG, increased HDL-c, decreasing insulin resistance. Moderate physical activity is recommended daily or at least one hour a day for 3 days a week of intense physical activity. Spending free time on TV should not exceed two hours per day. In children aged 1 to 5 years, watching TV with the family will be discouraged. Family activities should be undertaken at least once a week, encouraged especially in children aged 3 to 10 years (3, 6, 12).

Drug therapy

Starting lipid-lowering therapy is based on fasting LDL-c levels and the presence/absence of cardiovascular risk factors. Children and adolescents with LDLc ≥ 250 mg/dL and/or TG ≥ 500 mg/dL must be evaluated by a specialist to a proper management (11).

Drug therapy for high LDL-cholesterol

Patients with mildly elevated LDL-c, but with significant family history of premature cardiovascular disease (LDL-c ≥ 160 mg/dL, values older than 10 years, associated with risk factors) or with LDL-c ≥190 mg/dL, with no risk factors, might benefit from drug intervention (12).

The recommended treatment for reducing LDL-c is statins (13). As a rule, statins' therapy is not recommended before the age of 10 years, except for a high-risk family history, cardiovascular disease and/or premature events, the presence of one or more high risk factors or associated risk factors (6) (tab. IV).

TABLE IV

Treatment interventions for elevated LDL-c

LDL-c 130-189 mg/dL	Negative family history Without risk factors	Diet and lifestyle advice
LDL-c 130-159 mg/dL	2 high risk factors or 1 high risk factor + ≥ 2 moderate risk factors or BCV	Diet and medical therapy (statins)
LDL-c 160-189 mg/dL	1 very high-risk factor or ≥ 2 moderate risk factors or Positive family history	Diet and medical therapy (statins)
LDL-c ≥ 190 mg/dL	-	Diet and medical therapy (statins)

The treatment should start with the lowest available dose of statin, administered once daily (14). All statins, except Pitavastatin were approved by the Food and Drug Administration (FDA) in the USA in children with familial hypercholesterolemia. Pravastatin is used in children over 8 years, and all other statins (Simvastatin, Fluvastatin, Lovastatin, Atorvastatin, Rosuvastatin) were administered after the age of ten (1, 6) (tab. V).

The goal is to achieve a reduction in LDL-c levels below 130 mg/dL, ideally < 110 mg/dL. If the target is not reached, then the dose of statins should be increased (usually 10 mg), but with monitoring of liver transaminases (to be repeated every 4 weeks). If the LDL-c level remains high, the dose of statin may be increased. It must be considered that each doubling of the statins dose only leads to a reduction of about 6% of the LDL-c levels.

TABLE V

Indication for use of statins by age

Statins	Age	Dose
Atorvastatin	10-17 years	10-20 mg
Fluvastatin	10-16 years	20-80 mg
Lovastatin	10-17 years	10-40 mg
Pravastatin	8-13 years 14-18 years	20 mg 40 mg
Rosuvastatin	10-17 years	5-20 mg
Simvastatin	10-17 years	10-40 mg

Statin therapy monitoring requires a careful evaluation which will focus on

child growth and pubertal development (height, weight, BMI, Tanner staging), blood pressure and possible adverse effects. Laboratory investigations include lipid levels, liver function tests (ALT, TGO) and creatinkinase each month in the first year, twice a year in the coming years. In case of side effects, medication should be discontinued at least two weeks; later rechecked biological investigations, and if the side effects are solved, medication may be resumed with careful monitoring (4, 9).

If lifestyle changes combined with statin therapy was not successful, it may be added other lipid-lowering drugs. Ezetimibe is an inhibitor of cholesterol absorption, used in children with hypercholesterolemia over 10 years (5, 11, 15).

Drug therapy for elevated triglycerides

Children with elevated TG up to 500 mg/dL are at increased risk for pancreatitis. There is no consensus to prevent pancreatitis in people under 18 years of age with a significant risk. The European Experts Group recommends that administration of fibric acid derivatives and omega 3 fatty acids should be considered in association with nutritional counselling. There is data supporting that pre-prandial addition of Orlistat (Xenical), an inhibitor of pancreatic lipase, associated with a very low-fat diet is an effective way to prevent pancreatitis in people with familial lipoprotein lipase deficit. Adding omega 3 fatty acids can be useful to lower slightly elevated TG, but it has been not established an effective dose. The addition of 1g of omega-3 fatty acids is recommended for adults with cardiovascular disorders, but with minimal effect on reducing TG. Higher doses of omega-3 fatty acids may increase LDL-c levels despite the drop in total cholesterol (result of reducing triglyceride-rich lipoprotein cholesterol) (6, 16-18).

Drug therapy for mixed dyslipidemia

Although the major focus was on identifying and treating children with elevated LDL-C, the most commonly encountered dyslipidemia in clinical practice is hypertriglyceridemia associated with low HDL-c. This model of "atherogenic dyslipidemia" may be genetic and it is most commonly seen in children with obesity (BMI $\geq$ 95 percentile) and insulin resistance (manifested clinically by the presence of acanthosis nigricans, prediabetes, hypertension). It is noted that obesity may exacerbate genetic dyslipidemia and the atherosclerosis process. The safest and most effective treatment for acquired dyslipidemia consists in lifestyle changes, encouraging healthy eating habits, daily moderate to intense physical activity and weight reduction. Tobacco cessation and/or eliminating passive exposure to it can be a strategy for lowering cardiovascular risk in adolescents (17, 18).

Drug therapy for low HDL-cholesterol

Low HDL-c increase the risk of cardiovascular disease. Decreased HDL-c, frequent in obese children who have insulin resistance, is almost always associated with increased TG. There are no approved medical interventions in children with low HDL-c, others than mitigate the standard risk factors through lifestyle changes. In adult people, drugs aimed for raising HDL-c (e.g. transport cholesterol inhibitors or niacin) have not shown clinical efficacy (6-8).

CONCLUSIONS

According to actual guidelines, we recommend universal screening of dyslipidemia for all children aged 9-11 years, regardless of the general condition or the presence/absence of cardiovascular risk factors. The screening will allow us identifying the children with less severely elevated risk factors, in which intervention

will be more effective. Indications for treatment are based on the best available evidence and may be successfully on appropriate follow-up. Given the impact of early atherosclerosis onset in childhood and further cardiovascular complication, it is important that such recommendations to be consistently implemented by primary care providers and pediatrician. Continued implementation of public health programs is needed for the identification and treatment of cardiovascular risk factors in childhood.

THE SPECTRUM OF HISTOLOGIC FINDINGS IN HEPATIC OUTFLOW OBSTRUCTION

Budd-Chiari syndrome and cardiac (congestive) hepatopathy are the 2 most well-known diagnoses in the category of hepatic venous outflow obstruction. Although the 2 diseases differ in their clinical presentations, etiologies, and points of occlusion along the hepatic outflow tract, they show similar morphologic findings on sampling of patient liver tissue. Budd-Chiari syndrome refers to obstruction of the hepatic outflow tract, typically by thrombosis, anywhere from the hepatic venules to the junction of the inferior vena cava and right atrium. It occurs in approximately 0.001% of the population and has numerous potential etiologies, including inherited and acquired prothrombotic states, myeloproliferative diseases, and oral contraceptive use. Patients may present with acute, subacute, or chronic disease. The diagnosis can often be made clinically by radiologic demonstration of outflow obstruction, though patients with obstruction of intrahepatic veins may have normal findings on imaging. Pathologic changes in biopsied or explanted livers of patients with Budd-Chiari characteristically include perivenular necrosis, sinusoidal dilation, and occasionally formation of macronodules resembling focal nodular hyperplasia. In cardiac hepatopathy, right-sided heart failure of any cause prevents proper blood flow into the heart. This leads to a backlog of blood in the venae cavae and ultimately within the liver, causing intrahepatic congestion. This process causes the classic gross appearance of nutmeg liver, and longstanding congestion can lead to extensive fibrosis (termed either cardiac sclerosis or cardiac cirrhosis). The degree of cardiac dysfunction and severity of clinical presentation can vary widely, and as a result, cardiac hepatopathy may not be suspected clinically and therefore could progress undiagnosed. Patients under consideration for heart transplant may undergo liver biopsy to assess for the presence and severity of cardiac hepatopathy, as preoperative hepatic disease has been linked to postoperative morbidity. Biopsy findings include centrilobular and sinusoidal dilation and centrilobular necrosis, depending on the severity of the cardiac disease. A third type of hepatic outflow impairment, sinusoidal obstruction syndrome (previously termed veno-occlusive disease), occurs when the hepatic sinusoids or central veins become obstructed. Though originally described in Jamaican children with alkaloid-induced hepatotoxicity, it is most commonly seen in the setting of myeloablative therapy for hematopoietic stem cell transplantation. It demonstrates a characteristic histologic pattern, with acute disease typified by marked sinusoidal dilation and congestion, with loss of sinusoidal endothelium, and chronic disease demonstrating central vein occlusion. These clinicopathologic findings help distinguish it from Budd-Chiari syndrome and cardiac hepatopathy. Although Budd-Chiari and cardiac hepatopathy are typically diagnosed clinically, patients with occult disease may undergo liver biopsy for nonspecific findings, such as elevated liver enzymes. Given the overlap in histologic pattern in the 2 conditions, the study aimed to determine whether certain microscopic changes were significantly more common in either, allowing for distinction between their otherwise-similar microscopic appearances and facilitating identification of the diseases in patients without a definitive clinical diagnosis (Gonzalez RS,. Gilger MA, Huh WJ. The Spectrum of Histologic Findings in Hepatic Outflow Obstruction. Arch Pathol Lab Med. 2017; 141:98–103).

PLEUROPERICARDIAL CYST-CASE REPORT (Abstract). Cystic lesions within the pericardial space are rare and comprise 7% of the mediastinal masses. We present the case of a 71-year-old woman admitted to the Cardiovascular Rehabilitation Clinic of the Iasi Rehabilitation Hospital for palpitations and vertigo. A routine abdominal ultrasound was performed, which revealed in the 4th segment of the liver a 12-mm hyperechoic nodule suggestive for hemangioma and a round, well-defined 3cm lesion with a possible topography on the diaphragm. An echocardiography has been requested and the cardiac origin was refuted. The barium test showed that the lesion was not located in the gastrointestinal tract. Anteroposterior and latero-lateral chest radiographs were performed, but they did not reveal the tumor. Thus, we decided to visualize it by chest computer tomography with contrast that showed an oval, well-defined lesion of 30/25 mm with homogenous structure, without contrast medium uptake and signs of local aggressiveness in the middle mediastinum, retrocardiac, on the posterior aspect of right atrium, in relation to inferior vena cava and esophagus. The lesions most frequently met within this area are the pleuropericardial ones. Short-term and long-term prognosis is good. **Keywords:** PLEUROPERICARDIAL CYST, MEDIASTINAL TUMOR, PALPITATIONS.

Cystic lesions within the pericardial space are a rare entity and comprise 7% of the mediastinal masses (1). They are more frequently located in the right costophrenic angle (in 70% of the cases) than in the left costophrenic angle (in 10-40%) (2). The most frequently met are the pleuropericardial lesions. The first to describe the mesothelial cyst were Churchill and Mallory in 1937 and later, in 1940, Lambert reported a similar case, described as pericardial cyst (3). They are usually found in the third or fourth decades of life and males and females are equally affected (4).

CASE REPORT

We present the case of a 71-year-old woman without medical history of cardiovascular disease, who was admitted to the Cardiovascular Rehabilitation Clinic of the Iasi Rehabilitation Hospital for palpitations and vertigo. When admitted to the hospital, the patient presented: impaired general status, altered mental status, amnesia, blood pressure of 105/60 mmHg and a heart rate of 60/min, normal heart rhythm but with numerous extrasystoles. Because of this, Holter-ECG monitoring was recommended that revealed 3325 supraventricular ectopies

with 286 supraventricular bigeminy events and 3 supraventricular trigeminy events. Also, there have been observed 622 ventricular ectopies with 7 ventricular bigeminy events and 24 ventricular trigeminy events. An antiarrhythmic treatment was initiated with favorable outcome.

A routine abdominal ultrasound was performed, which revealed in the 4th segment of the liver a 12mm hyperechoic nodule suggestive of hemangioma and a round and well-defined 3 cm lesion with a possible topography on the diaphragm. Because its location could not be established, an echocardiography was requested and the cardiac origin was refuted. Then a barium test was performed that showed that the lesion was not located in the gastrointestinal tract. We have also done an antero-posterior and latero-lateral thoracic radiography, but neither this investigation showed the tumor. Thus, we decided to visualize it by chest computer tomography with contrast that showed an oval, well-defined lesion of 30/25 mm with homogenous structure, without contrast medium uptake and signs of local aggressiveness in the middle mediastinum, retrocardiac, on the posterior aspect of right atrium, in relation to inferior vena cava and esophagus. The lesion had benign characters (pleuropericardial cyst).

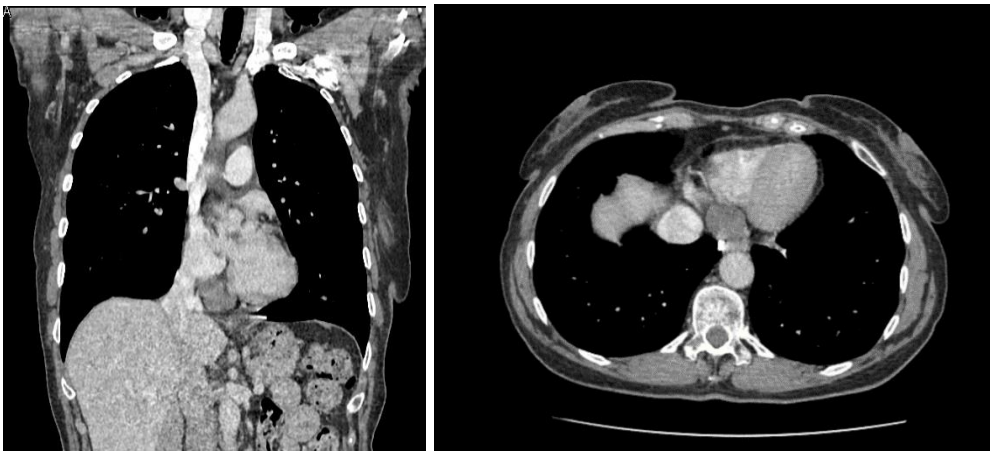

Fig. 1. Pleuropericardial cyst

DISCUSSION

From a theoretical point of view, the mediastinum is divided into 9 regions by 2 vertical planes and 2 horizontal planes into superior, middle and inferior and anterior, middle and posterior. In our patient's case, we had to make the differential diagnosis of the anteroinferior region in which there can be found the endothoracic fascia, inferior pericardial ligament, phrenopericardial ligaments, heart and pericardium (5). It is known that the mediastinum contains numerous vital structures in a relatively small area and has a limited accessibility. At least half of the patients with mediastinal tumors are asymptomatic and the lesions are usually detected incidentally on chest radiographs or other routine laboratory investigations. The asymptomatic lesions are usually benign. The symptoms commonly appear after the compression or invasion of the adjacent organs (6).

The main symptoms that can be observed after the compression or invasion of the bronchial tree are: pain, cough, dyspnea, hemoptysis, dysphonia, wheezing; also, the venous compression determines the superior vena cava syndrome, azygos vein syndrome, thoracic duct syndrome, Menetrier syndrome, bilateral pleural effusion or lower limb edema. There can also appear signs of nervous compression expressed by dysphonia, hemidiaphragm paralysis, hiccups, intercostal neuralgia, Claude Bernard Horner syndrome, Pancoast Tobias syndrome. In addition, we can find tachycardia and palpitations as circulatory signs and, last but not least, dysphagia. Occasionally, mediastinal tumors may manifest clinically as paraneoplastic syndromes, most frequently endocrine (7).

In our patient's case, we considered the following differential diagnosis:

- Pleuropericardial cyst - a mesothelial cyst that grows from the parietal pericardium. It is asymptomatic, being frequently discovered incidentally. It is in the anterior costophrenic angle, predominantly right sided. Chest radiograph reveals a well-defined homogenous opacity, moving with respiration;
- Diaphragmatic relaxation or eventration, determined by the deficient development of the phrenic nerves that reach the muscles and are often located in the antero-median region of the right hemidiaphragm; this was refuted in our case by computer tomography;
- Morgagni hernia that is determined by a defect in the parasternal region of the diaphragm, usually on the right side. Chest radiograph shows well-defined right paracardiac opacity of variable intensity depending on the content (8), negative in our case.

Short- and long-term prognosis is good. Among the most frequent complications we should mention compression, inflammation, rupture and hemorrhage. Intracystic hemorrhage may be spontaneous or post-traumatic. Hemorrhage may determine a quick expansion of the cyst and may culminate with severe pain, cardiac tamponade or congestive heart failure (9, 10, 11).

CONCLUSIONS

Our case is a useful opportunity for clinical remarks firstly given its atypical onset - this cyst was detected incidentally in the seventh decade of life, it was localized on the left side, contrary to most the cases in the literature. In addition, we should take into consideration the fact that in our patient we could not see anything on the chest radiograph, even if in the literature many cases are discovered through this investigation.

LONGER CORONARY ANASTOMOSIS PROVIDES LOWER ENERGY LOSS IN CORONARY ARTERY BYPASS GRAFTING

The first successful CABG intervention was performed in 1964 by Michael DeBakey who bypassed a coronary stenosis by interposing a saphenous vein graft between the ascending aorta and the diseased coronary artery distal to the lesion. Since then, the technique evolved and nowadays the intervention can be performed off-pump and minimally invasive. Despite all progress, clinical studies did not manage to identify the ideal grafting technique in terms of grafting configuration, graft type, graft harvesting, graft preparation, anastomoses, and optimal long-term patency. Distal anastomosis technique has been proved to affect long-term graft patency by numerous studies. However, the appropriate length of distal anastomosis has not been investigated until the research performed by dr. Hiroyuki Tsukui and his collaborators. Their study aimed to evaluate whether longer distal anastomosis provides higher quality of distal anastomosis and better hemodynamic patterns. For this purpose they used a CABG training simulator for building distal anastomosis models. The authors prepared two end-to-side distal anastomosis models of different lengths (10 versus 4 mm) and used computed tomography (CT) to obtain a 3D reconstruction of the inner shape of distal anastomosis. Afterwards, computational flow dynamics (CFD) was used to analyze hemodynamic patterns. The 3D CT reconstruction showed that the quality of distal anastomosis in the 10 mm model was more uniform without vessel wall inversion or kinking compared to 4 mm model. Anastomotic flow area proved to be significantly larger in the 10 mm model compared to the 4 mm one. Also, the anastomotic angle was smaller in 10 mm model compared to 4 mm model, a condition associated with lesser flow turbulences. CFD analysis demonstrated that the 10 mm model had streamlined flow with smooth graft curvature, whereas 4 mm model had abrupt blood flow with directional changes and separation at the toe. Subsequently, the 10 mm model registered a lower energy loss than the 4 mm model. The authors concluded that longer distal anastomosis provided a larger anastomotic flow area, a smaller anastomotic angle, and smoother graft curvatures, factors associated with a higher flow quality and better long-term patency. (Tsukui H, Shinke M, Park YK, Yamazaki K. Longer coronary anastomosis provides lower energy loss in coronary artery bypass grafting. *Heart Vessels*. 2016; 32(1): 83-89).

RARE CAUSE OF RHABDOMYOLYSIS-CASE REPORT (Abstract): Rhabdomyolysis, a syndrome caused by injury to the skeletal muscles, is a condition associated with various signs ranging in from asymptomatic elevation of serum creatine-kinase to acute kidney injury, abnormal heart rate and rhythm, coma and even death. We report the case of a 52-year-old woman who developed rhabdomyolysis following an epileptic seizure. Because a single epileptic seizure does not commonly cause rhabdomyolysis, we tried to identify other contributing factors. The only finding was an electrolyte imbalance due to vomiting. This case had a favorable outcome. Our report highlights the importance of considering rhabdomyolysis in a patient with a recent epileptic seizure, especially when several trigger factors for rhabdomyolysis act simultaneously in the same patient. **Keywords:** RHABDOMYOLYSIS, EPILEPSY, SEIZURE.

Rhabdomyolysis is a syndrome caused by injury to the skeletal muscles. It is a potentially life-threatening condition because the breakdown products of damaged muscle cells are released into the bloodstream. Myoglobin is potentially harmful to the kidneys and within 12 to 24 hours after the initial muscle damage may lead to acute kidney injury (AKI). The risk of developing AKI can be as high as 40% (1). Rhabdomyolysis is believed to be responsible for up to 15% of all cases of AKI (2). Myoglobin has a direct nephrotoxic effect due to its activity as a peroxidase-like enzyme. By interacting with Tamm-Horsfall protein it creates casts that are obstructing the tubule (3). The electrolyte imbalance is responsible for nausea and vomiting, altered mental status ranging from confusion to coma, abnormal heart rate and rhythm. Hyperpotassemia can lead to cardiac conduction impairment, which can cause ventricular fibrillation, abnormally slow heart rhythms and asystole.

CASE REPORT

We report the case of a 52-year-old woman who developed rhabdomyolysis following an epileptic seizure.

The patient had a history of high blood pressure. Over several days, she had acute nausea and vomiting due to inappropriate diet. She was brought to hospital by ambulance after experiencing an episode of tonic-clonic seizure at home. No signs of meningeal irritation or focal neurological

deficit were present. The CT scan excluded any posttraumatic cranio-cerebral injuries, stroke and intracranial expansive processes. Neurological examination made a clear diagnosis of epilepsy.

Chest X-ray ruled out pleural and lung lesions. EKG was normal and transthoracic echocardiography showed only hypertension-induced changes. Abdominal ultrasound did not reveal anything significant.

Patient's initial laboratory assessment showed very high levels of creatine-kinase (45852 U/L), hypokalemia (K=2,7 mmol/l) and sodium, calcium and chlorine levels slightly below the limit values. The highest level of TGO was 606 U/L, of TGP 136 U/L and LDH 1259 U/L. Renal function and uric acid levels were within normal range. Tests for hepatitis virus B and C turned out negative. Thyroid function was normal and no signs of primary hyperaldosteronism were found. The patient denied both alcohol consumption and drug administration at home.

The patient was well hydrated with oral and iv fluids and the electrolyte imbalance was restored. She was closely monitored clinically and by laboratory tests. The case had a favorable outcome, the creatine-kinase (CK) levels gradually decreased, the renal function remained unaltered and there were no consequences of electrolyte abnormalities.

DISCUSSION

Rhabdomyolysis can have many causes and may take various forms, ranging from asymptomatic elevations of serum muscle enzymes to a life-threatening condition.

Causes of rhabdomyolysis can be: *trauma* („Crush syndrome"), *prolonged immobilization* (in elderly people or after stroke or surgery), *exertion* (extreme physical exercise, delirium tremens, tetanus, prolonged seizures or status epilepticus), *extreme body temperature* (malignant hyperthermia, severe hypothermia), *drugs* (statins, fibrates, diuretics, antipsychotic medications, neuromuscular blocking agents used in anesthesia, selective serotonin reuptake inhibitors, abuse of alcohol, amphetamine, cocaine, heroin, LSD, ecstasy), *toxins* (heavy metals, venom from insects or snakes, poisonous plants), *muscle hipoxia* (blocked arterial flow), *metabolic imbalances* (hyperglycemic hyperosmolar state, hyper- and hyponatremia, hypokalemia, hypocalcemia, hypophosphatemia, ketoacidosis, hyperaldosteronism, hypo thyroidism), *autoimmune muscle damage* (polymyositis, dermatomyositis), *infections*, *genetic defects* (4).

Plasma myoglobin increases rapidly after muscle injury, but is quickly cleared by kidneys and a normal level is reached within 24 hours. Because of its short half-life, plasma myoglobin is not as sensitive as CK for diagnosis. The CK levels increase within the first 12 hours after muscle injury, remain elevated for 3–5 days and then gradually fall over the subsequent 6–10 days (5). Therefore, serum CK level is the most reliable test in the diagnosis of rhabdomyolysis. CK levels 5 times higher than the upper limit (i.e. 1.000 IU/L) clearly indicate rhabdomyolysis. The risk of AKI has a linear relationship with the initial and peak CK levels. The higher the CK level, the more likely the AKI will occur, but there is no specific CK level above which AKI occurs (6). Usually levels below 20.000 U/l are unlikely to induce kidney impairment, unless there are other contributing risk factors.

A single epileptic seizure does not commonly cause rhabdomyolysis (7), most

of the cases reported in the literature being due to status epilepticus. However, the muscle forces generated during tonic-clonic seizures alone can cause severe muscle injury. Rhabdomyolysis is also a result of fall during seizures as most of the time falls lead to muscle trauma. Please note that our patient did not show any evidence of direct trauma.

It is important to observe that rhabdomyolysis has been associated with a variety of electrolyte disorders, particularly hypokalemia. Severe electrolyte abnormalities disrupt cell membrane homeostasis, mainly by disturbing the Na/K ATPase pump activity. Hyponatremia (8), hypernatremia (9), hypokalemia (10) and hypophosphatemia (11) may result in rhabdomyolysis. Potassium plays a major role in regulating the skeletal muscle blood flow. Potassium released from muscle cells during exercise normally mediates vasodilation and appropriately increases the blood flow to the muscles. Decreased potassium release due to hypokalemia may promote the development of rhabdomyolysis by decreasing blood flow to the muscles (12, 13). In addition to hypo perfusion, hypokalemia-induced impairment in muscle metabolism may also contribute to muscle dysfunction.

In the here reported case, we strongly believe that the highly-elevated levels of CK (230 times higher than the upper limit) are explained by the combined action of two trigger factors for rhabdomyolysis: seizure and the preexisting electrolyte imbalance, mainly hypokalemia (due to vomiting). In the literature, we found only one case reporting hypokalemia due to vomiting as the single cause of rhabdomyolysis (13).

The prognosis of rhabdomyolysis is heavily dependent on the underlying etiology and associated comorbidities. Despite the lack of any well-organized prospective studies, the available evidence suggests that rhabdomyolysis has an excellent prognosis when treated early and aggressively (14). Moreover, when kidney function is impaired, the prognosis for the full renal function recovery is excellent (3). Fluid resuscitation must be initiated as soon as possible as the fundamental therapeutic measure to prevent AKI.

CONCLUSIONS

Our case report highlights the importance of considering rhabdomyolysis in a patient with a recent epileptic seizure, especially when several trigger factors for rhabdomyolysis act simultaneously in the same patient. Early evidence of this phenomenon provides the chance of preventing irreversible kidney damage by appropriate therapeutic measures, which are simple and worldwide available.

COULD CBCT REPLACE CLASSIC CT IMAGING IN PATIENTS WITH OTOSCLEROSIS?

Otosclerosis is a primary disease of the otic capsule, characterized by alternating phases of absorption of compact bony tissue and replacement with spongy bone. A study of 43 patients with stapes ankilosis, explored by CBCT and HRCT was made with the aim of comparing the diagnostic value of CBCT and HRCT in the preoperative evaluation of otosclerosis. Histologically active otosclerosis (n=23) was detected equally by both HRCT and CBCT. However, CBCT was unable to detected histologically inactive otosclerosis (n=12). In conclusion, HRCT remains the first choice in the imaging diagnosis of otosclerosis. However, CBCT is also a reliable diagnostic tool, continuously evolving by introduction of more powerfull analyser softwares and has the advantage of providing high quality images, with exclusively scanning the examed zone, at a considerably lower radiation dose than HRCT (Révész, P., Liktor, B., Liktor, B. et al. Could cbct replace classic ct imaging in patients with otosclerosis? *Eur Arch Otorhinolaryngol* (2016) 273: 63. doi:10.1007/s00405-015-3490-3).

Department of Mother and Child Medicine

EXCESSIVE PRIMARY POSTPARTUM HEMORRHAGE (Abstract). The diagnosis and treatment of excessive bleeding within the first 24 hours after delivery and its main causes, namely uterine atony, retained placental fragments, vascular lesions by local tissue rupture, and blood clotting disorder are presented. Of great interest is the iconography, which is suggestive and original. **Keywords**: EXCESSIVE, OBSTETRIC, HEMORRHAGE, IMMEDIATE POSTPARTUM.

Excessive primary postpartum hemorrhage (after vaginal or C-section delivery) is often accompanied by an abnormal prenatal coagulogram (specific for obstetrics), which can be a warning sign. It has four major causes: uterine atony (in the case of malformed uterus, fibromyomatous uterus, over-distended uterus due to multiple pregnancy, polyhydramnios or fetal macrosomia, uterine muscle exhaustion after prolonged labor or uterus of an obese mother); retained placental or membrane fragments; uterine rupture, tears of the cervix, vagina, vulva, pelvic floor; coagulation disorders, most commonly disseminated intravascular coagulation (DIC) and secondary fibrinolysis in: uteroplacental apoplexy, dead fetus in utero, amniotic fluid embolism, chorioamnionitis, septic shock, even a severe acute hemorrhage, hemorrhagic shock, *placenta previa*, *placenta accreta*, preeclampsia-eclampsia etc. Bleeding can be external, internal or mixed.

Clinical causal assessment:

- uterus greater than 20 cm/10 cm; low uterine tone – examination of placenta and membranes (evidence of missing placental fragments, membranes);
- coagulability or non-coagulability of blood in the renal pelvis;
- examination of the birth canal: manual exploration of the uterine cavity (for the presence or absence of retained placental fragments and uterine rupture);
- speculum exam for cervical tears; inspection of the external genitalia and perineum.

Simple tests that can quickly pinpoint the diagnosis (1):

- Low platelet count: 15-20,000 indicate a DIC;
- Collection of blood in a 3.5 ml test tube without anticoagulant:
- a small clot with a red blood cells deposit formed at bottom of the tube suggests DIC;
- a clotting time (CT) exceeding 10 minutes means a drop of fibrinogen level below 100 mg%;
- clot formation and its resolution within 30 minutes denotes secondary fibrinolysis;
- the total non-coagulability of blood is indicative of primary fibrinolysis. These tests require laboratory confirmation (1).

Management of uterine atonia:

- compression of abdominal aorta for 5-15 minutes, uterine massage;
- in the already installed IV infusion set introduce 10-15 U oxytocin and/or ergometrine or methergin 0.2 mg or intramuscularly 15-methyl PGF_2; bleeding persists or recurs.

The uterine cavity is explored manually (for removing the retained placental fragments and checking for uterine tears, especially after manual detachment and removal of placenta or other obstetrical procedure or maneuver. If the uterus is intact, introduce your right hand into the uterine cavity, clench your fist and use the other hand to massage the uterus through the abdominal wall. If the bleeding persists inject ergomet or prostaglandins PGE_2 or PGF_2 into the cervix (1).

Prostaglandins PGE_2, PGF_2, and PG_{2a} can be injected most effectively intramyometrially, into the cervix or intravenously and prostaglandin analogue sulprostone (15-methyl PG_{2a}) intramuscularly (1).

It is preferable that intramyometrial (and into the cervix) or intravenous injections to be made after the manual inspection of the uterine cavity. Bleeding persists. Grasp the cervix with forceps (with six claws) into the four cardinal points and use them to strongly pull it down (thus an angle bend of the uterine artery that diminishes the bleeding is obtained). In modern obstetrics, intrauterine message is no longer indicated (2).

In addition to these procedures, Luca (1) mentions the placement of hemostatic threads in "X" on the cervicoisthimic junctions or Henckel forceps on commissures.

In parallel the following are done: correction of volemia, the necessary volemic expansion with blood transfusions (blood collected within the last 6 hours), fresh frozen plasma (thawed), macromolecular solutions, isotonic NaCl or glucose solutions, and correction of coagulability.

Inspection of the uterine cavity is also indicated in case of tears of cervical commissures extending to the vaginal fornix in order to detect a possible commissural tear on the lateral aspect of the segment. If the uterus is not intact, a median sub umbilical laparotomy is performed.

Recent linear segmental cervical ruptures, without infiltration of the myometrial walls, with vaginal wall disinsertion and without broad ligament hematoma are managed by segmentoraphy plus suture of the intravaginal part of the cervix, followed by reinsertion of the detached portion of the vagina and abdominal drainage (plastic tube).

Uterine rupture accompanied by ileal pelvic hematoma increasing in size requires the identification of ureteral tract, external iliac artery and hypogastric artery with ligation of the latter to control the bleeding vessel responsible for causing hematoma. Identification of this vessel when pelvic anatomy is distorted by disease is very challenging, very bloody and very dangerous for ureter. For these reasons *bilateral hypogastric artery ligation* (BHAL) should be performed (3).

In extensive repairs, after protective hypogastric artery ligation, in case of an anfractuous rupture with wide myometrial serohematic infiltration or signs of infection, degenerative lesions (apoplectic), *placenta previa* (frequently accreta) or *placenta accreta*, total hemostatic hysterectomy is performed followed by adnexectomy on hematoma side only in case of massive hemorrhagic infiltration of adnexa. The next step is hematoma removal and hemostatic drainage of hematoma area and pelvis with externalization of the surgical dressing through vaginal section with visceral peritonization (4).

In case of rupture of the uterine cervix, vagina, vulva and pelvic perineal-floor a hemostatic suture is performed.

Blood clotting disorders

The risk of excessive postpartum bleeding is higher in mothers with preexisting clotting disorders (such as idiopathic thrombocytopenic purpura, Willebrand disease, prothrombin complex deficiency) or most commonly in those presenting a disease at risk of hemorrhagic events by disseminated intravascular coagulation and secondary fibrinolysis, such as: uteroplacental apoplexy, fetal death and retention of dead fetus in utero, chorioamnionitis, septic shock, placenta previa or accreta, amniotic embolism, preeclampsia, eclampsia or even the associated severe bleeding, hemorrhagic shock, etc.

Thus, if after delivery mother's blood hemostasis is within normal range, then prompt surgical hemostasis (as soon as possible after the occurrence of bleeding) is the essential therapeutic factor and must be associated with volemic restoration (expansion) with crystalloid solutions, macromolecular solutions, fresh blood (preferably collected within the last 6 hours), fresh frozen plasma (thawed), cryoprecipitate (containing fibrinogen, factor VIII, accelerators), platelet concentrates etc. Thus, hemorrhagic shock can be prevented or reversed (5).

Abundant bleeding with clotting disorders is approached in the same manner. The essential part of therapy is prompt surgical hemostasis ("save blood") concomitant with the replacement of the lost circulating blood with fresh blood, fresh frozen plasma (thawed) in a higher proportion to the volume lost; fresh blood and fresh frozen plasma (thawed) provide coagulation factors (fibrinogen, factors VIII, V, etc.), macromolecular solutions, cryoprecipitate (administered if fibrinogen level is less than 100 mg%), platelet concentrates (administered if platelet count is below 60,000/mm). These are the primary and basic therapy of the hemorrhage syndrome.

In addition to these, in excessive secondary fibrinolysis (strongly confirmed by very short ECLT-euglobulin clot lysis time), Merger et al. (6) recommend the administration antifibryonolitic drugs, such as Iniprol or Trasylol (50-100,000 U). Arias (7) suggested that "there is no place for the use of heparin in obstetric hemorrhages". Luca (2000) showed that in trans catheter embolization of hypogastric arteries, the procedure time of selective catheterization is 1-2 hours (to be well done) and this time is often fatal. EACA (*Epsilon-aminocaproic acid*) is contraindicated (1).

In severe cases when even on correct treatment bleeding persists, bilateral uterine artery ligation (on the lateral margins of uterus), the bilateral hypogastric artery ligation, total hysterectomy and the pelvic excavation packed tightly with gauze should be performed (8).

Statistics show that of hysterectomies, the subtotal one is obviously most frequently performed (especially for uterine atonia). However, total hysterectomy is performed in cases of uteroplacental apoplexy, placenta previa, placenta accreta, irregular uterine rupture propagated towards the cervix, signs of infection and wide areas of serohematic infiltration within the myometrium.

BHAL results in a decrease in blood pressure in the hypogastric artery branches. During an operation for cervical cancer and pregnancy, in which we performed a preventive hypogastric artery ligation, we found that there was blood flow through the sectioned uterine artery, but pressure was much lower.

Figure 1 shows the trajectory of parietal peritoneal incision (dotted) for the surgical approach of hypogastric artery (uterovesical trunk, peritoneal incision, hypogastric artery external iliac artery, ureter, suspensory ligament of ovary).

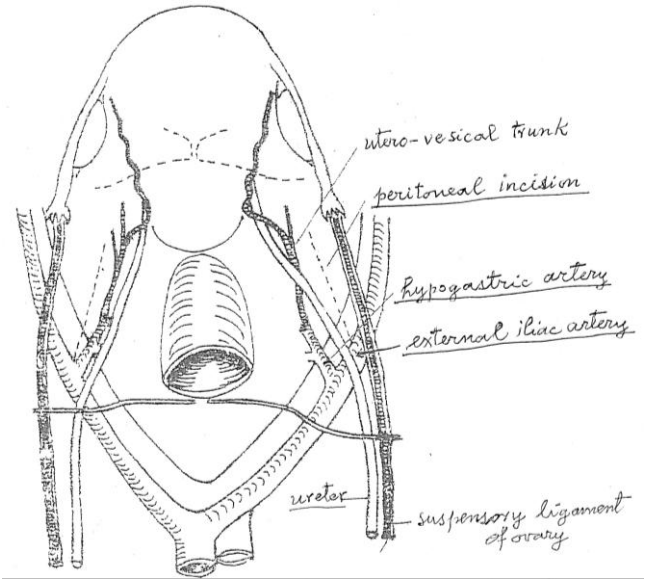

Fig. 1. Trajectory of parietal peritoneal incision (dotted) for the surgical approach of hypogastric artery

Figure 2 is illustrative for median sub umbilical laparotomy. The uterus is inverted over symphysis pubis and compresses it and the hands of the surgeon assistant simultaneously compress the lateral margins of the uterus (inferior side) thus blocking the flow in the ascending branches of the uterine arteries and reducing uterine bleeding.

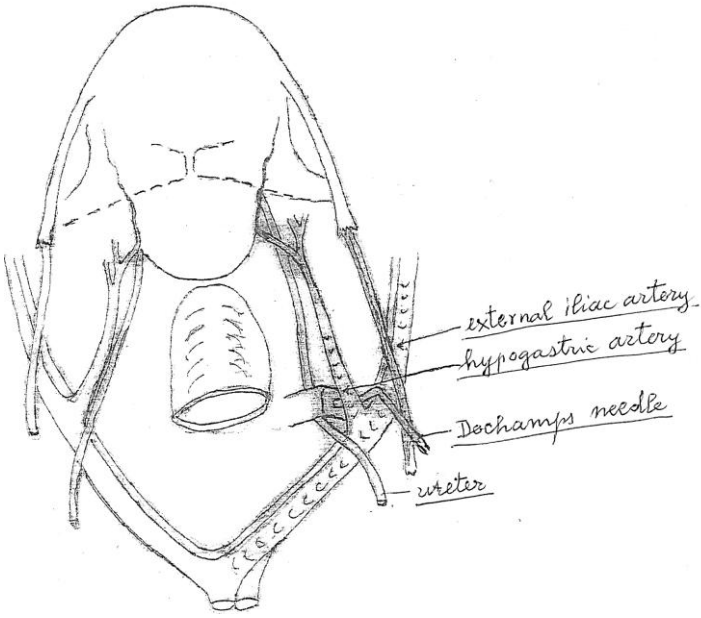

Fig. 2. Hypogastric artery ligation

This way, a provisional uterine hemostasis necessary for performing BHAL is achieved and the pelvis is released (to make BHAL possible). The surgeon will check for surgical hemostasis and clotting at normal blood pressure at the end of surgery.

It should be recalled that in case of a clotting disorder, hemostatic hysterectomy produces new and multiple dangerous hemorrhagic foci (6). That is why it is imperative the clotting disorder to be corrected before hysterectomy.

If hemostasis is uncertain and patient's condition allows it BHAL can be performed before closing the abdominal wall to ensure hemostasis in the postoperative period and avoid reoperation (when BHAL is the only option) (9).

By decreasing blood pressure in the arteries, a clot forming at the level of a vascular continuity solution or in small vessels, or even a platelet plug cannot be grabbed and removed.

CONCLUSIONS

Bilateral hypogastric artery ligation is sometimes effective in achieving hemostasis when performed earlier, reducing intraoperative bleeding and making hemostatic hysterectomy unnecessary. But when the mother is at immediate vital risk, hemostasis can be achieved only by hysterectomy, while by BHAL hemostasis it can be achieved only sometimes.

BHAL reduces bleeding during hemostatic hysterectomy. Thus, BHAL is performed earlier so that in case of failure to have time to perform a hysterectomy

CLASIC VERSUS NOVEL IN REDUCTION OF ACUTE ANTERIOR DISLOCATION OF THE SHOULDER: A COMPARISON OF FOUR REDUCTION TECHNIQUES (Abstract) **Aim**: The purpose of our study is to compare four different techniques for reduction shoulder dislocation in term of efficacy, duration until reduction and pain felt by patient during the procedure. **Material and methods:** During 2015 year, we conducted a study on 50 chronological patients with anterior shoulder dislocation. After exclusion of four patients, the remaining 46 (74% males, mean age 44.6±20.03 years, range 18 to 89) were randomly assigned in four groups and reduced by Cunningham (C), Kocher (K), Mothes (M) and Hipocrat (H) techniques. All the patients were sedated using Midazolam (2 mg) and Fentanyl (1µg/kgbw) except patients who underwent Cunningham technique. **Results:** The success rate was 76.9% in C group, 98.4% in K group, 90.2% in M group and 87.96% in H group ($p>0.05$). The level of pain in C group was similar to the other groups in the absence of pain medication ($p<0.05$) **Conclusions:** Cunningham technique is a simple, single person technique, drug free, less painful and safer, comparable with other "classical" methods. **Keywords:** ANTERIOR SHOULDER DISLOCATION, CLOSED REDUCTION, SCAPULAR MANIPULATION.

Due to particularly high mobility, shoulder is the most dislocated joint, with a prevalence of 17 per 100,000 individuals; approximately 95% of these dislocations are anterior (1). Various reduction techniques have been described with different rates of success and complications. Most of them are variants of what we consider "classic techniques" described by Kocher (2, 3), Mothes (4), Hipocrat (5, 6, 7) which include traction-counter traction and leverage maneuvers, some are considered "novel techniques" such scapular manipulation (8) and Cunningham (9) based principles of static and dynamic obstruction on the humeral head. The ideal technique should be quick, effective, painless and not cause further injury (10).

Although not all the dislocated shoulder need pain medication, for ethical and legal reasons, the reduction technique should be performed under local or general anesthesia, as soon as possible (11, 12). In the Emergency Department, intravenous administration of opioids and benzodiazepine is commonly used. Although it ensure painless reduction, these drugs have important side effects such as respiratory distress,

hypotension, bronchospasm, which need close respiratory and cardiac monitoring of patients.

There are some clinical trials regarding reduction of scapular dislocation especially in the United States but none of our knowledge about compared efficacy of these four reduction techniques.

The aim of our study is to compare the efficacy of four reduction techniques for anterior shoulder dislocation: Cunningham, Kocher, Mothes and Hipocrat, in terms of time until reduction, post reduction pain and complications.

MATERIAL AND METHODS

We conducted a study in the Emergency Department of "Saint Spyridon" Clinical Emergency Hospital during 2015, according to the guidelines of "Grigore T. Popa" University Committee for Research and Ethical Issues, on 50 consecutive patients with anterior shoulder dislocation. Two polytrauma patients and two Neer III fracture–dislocation patients were excluded.

All the patients were examined before and after the reduction for vascular and neurological lesions. After clinical and radiological diagnosis (anteroposterior view), patients were randomized by drawing envelopes to undergo reduction of the dislocation with one of the four methods used in the study by a single team of orthopedic surgeons.

Inclusion criteria: anterior shoulder dislocation with or without fracture of the great tuberosity, same reduction team, age above 18 and below 90 years.

Exclusion criteria: polytrauma patients, three or four part fracture dislocation, admitting more than 24 hours after the trauma, hypersensitivity to Midazolam or Fentanyl, severe cardiovascular or pulmonary disease, intake of food or fluid during last 4 hours; presence of airway difficulty; sensory problems; motor problems, vascular problems, and consumption of alcohol or other recreational drugs.

The patients undergoing Kocher (K), Mothes (M) and Hipocrat (H) techniques were sedated using Midazolam (2 mg) and Fentanyl (1μg/kgc). For Cunningham (C) technique, all the patients were informed about the procedure and express their consent for reduction. All subjects remained verbally responsive during the procedure.

All methods of reduction were performed as described by their authors. The unsuccessful cases were treated by Kocher reduction. In case of failure, patients were treated close reduction in operating room under general anesthesia.

All patients were cardiac and oxygen saturation monitored during the procedure. After reduction all the patients were immobilized in Velpeau bandage.

The quality of reduction was radiological evaluated (anteroposterior view). The patients were assessed by term of pain during reduction by visual analog scale (VAS) after they became fully oriented.

The patients were discharged after they had fully recovered orientation of time and space with vital signs within the normal range.

Statistical analyses were performed on *SPSS 20.0* version (SPSS Inc., Chicago, Illinois, USA). Patient characteristics were expressed as the mean standard deviation or as a number and percentage. Variables were compared by paired t test. A p value of less than 0.05 was considered statistically significant.

RESULTS

There were no statistically significant

differences between the four groups in terms of age, sex, primary-to-recurrent dislocations ratio, the mechanism of dislocation, the presence or absence of a coexisting fracture of the greater tuberosity, the mean time interval between the injury and the first attempt at reduction, and the reduction time (tab. I)

TABLE I
Clinical characteristic of patients in the four groups

Groups		K (n=13)	M (n=8)	H (n=12)	C (n=13)
Age (years) (Mean±SD)		35.8 ±18.7	44.6±20	47.9±40.6	44.2±19.8
Sex (%)	M	92.3	75	58.4	69,3
	F	7.7	25	41.6	30,7
Origin	Urban	46	37.5	25	38,4
	Rural	54	62.5	75	61,6
Mechanism	Sport activity	85	75	25	38
	Fall	15	25	75	62
Type	Primary	92.3	87.5	75	84,7
	Recurrent	7.7	12.5	25	15,3
Associated fracture		1	0	3	0

There was no vascular or neurological deficits pre or post reduction. Four patients (8,69%) had a great tuberosity fracture which was reduced orthopedic and did not required surgical reduction and fixation. One patient necessitates reduction under general anesthesia in operating room.

The duration of reduction was significantly different between the four groups (tab. II).

TABLE II
Efficacy, time needed for reduction and level of pain felt during the reduction

Groups	Reduction success rate		Time until reduction	Level of pain
	n	%		
K	12	98.4	116.3±41.7	3.38±1.04
M	7	87.5	181.8±57.9	3.25±1.03
H	11	91.66	69.91±15.8	2.33±2.21
C	11	76.92	287.9±126.4	3.07±1.11
p value			0.68	<0.01

DISCUSSION

To our knowledge this is the first study that compares these four techniques. Although it is traditionally belief that the reduction of shoulder dislocation necessitates traction and counter traction in term of force to overcome muscle contracture, there are techniques that do not imply force with

similar success rates (9, 13, 14, 15, 17, 19).

The lower success rate in our study with Cunningham technique and longer time until reduction compared with other technique, it`s probably motivated by a longer learning curve.

While the "classical" techniques of shoulder reduction require pain medication for the reduction to be achieved in terms of patient safety, we obtained significant comparative pain levels without sedation. Cunningham technique has the advantage of being less painful without the health risks (9).

In our study we did not evaluate time spent in the emergency department but it`s evidently shorter in Cunningham group.

Our study has some limitations. We included a small number of patients and the study was unblinded. We must consider that Midazolam has the side effect of anterograde amnesia and it becomes difficult to assess lever of pain on these patients.

Compared to others "classical" techniques, Cunningham have lower rates of mechanical complications (9). Although Kocher technique had a 98, 4% success rate in our study it`s known as unphysiological, brutal, and dangerous because of its association with fractures of the surgical neck of the humerus and neurovascular complications (11, 17, 18).

CONCLUSIONS

Although larger patient studies are necessary for confirmation, Cunningham technique should be considered because it's single person, drug free, less painful and safer, comparable with other "classical" methods.

NEWS

IS THERE ANY SUCH THING AS "NO EVIDENCE OF DISEASE ACTIVITY IN MULTIPLE SCLEROSIS"?

No evidence of disease activity (NEDA) in Multiple Sclerosis (MS) is a concept that has emerged throughout the last years as a result to new and effective therapies. The concept includes parameters such as freedom of relapse, stability on the Expanded Disability Status Scale (EDSS) – no sign of clinically worsening, as well as a stop of dissemination in time and space of demyelinating lesions on the MRI. Nevertheless, this is not enough to appreciate NEDA, as bedside relapse rate, disability progression and neuropsychological aspects such as cognitive status, depression, fatigue and quality of life are parameters also to be considered in the attempt of a better definition of the phenomenon. For all that, a multiple sclerosis decision model (MSDM) that would include all of these items to be evaluated, promises to support early treatment decisions. However, prospective studies are still required (Stangel M, Penner IK, Kallmann BA et al, Towards the implementation of 'no evidence of disease activity' in multiple sclerosis treatment: the multiple sclerosis decision model, *The Adv Neurol Disord.* 2015 Jan; 8(1): 3–13).

COMPLEX MANAGEMENT OF FRAILTY FRACTURES – CASE REPORT (Abstract): Frailty fractures encompass pelvic ring fractures in the elderly - a condition more frequently encountered in women, usually with pre-existing osteoporosis. The incidence of these fractures is increasing, following the increase in average life expectancy. Most of the times, they are the result of a minor injury, of which the patient has little or no recollection; the clinical signs and symptoms, radiological changes and the degree of fracture stability vary greatly. As such, there is a wide range of therapeutic options and one of the most important decisions for the physician is choosing between surgery and conservative treatment. We present the case of an elderly female patient with multiple pelvic ring fractures, and a medical history of cardiovascular disease and osteoporosis; the orthopedic examination recommended conservative treatment which was carried out in the Geriatric Clinic of the "Dr. C.I. Parhon" Hospital. Following the complete physical examination and through geriatric evaluation, a complex therapeutic plan was devised, which included: recovery through physiotherapy, adequate nutrition, psychological support, treatment of the cardiovascular comorbidities and prevention of the consequences of extended bed rest. The treatment lasted for 60 days and the outcome was favorable: decreased bone frailty, mainly through preserving muscle tone and osteoarticular function, correction of malnutrition, improvement of depression and partial recovery of patient's mobility; the results of our therapy made it possible for the patient to return home, where she leaves alone. She will need help with daily household chores, but she intends to continue the recovery therapy as means of increasing her quality of life and independence. **Keywords:** FRAILTY FRACTURES, SENIOR PATIENTS, RECOVERY THERAPY.

As the elderly segment of the population increases, so does the incidence of geriatric syndromes. Consequently, their impact on the medical services is more and more taxing, especially in the case of osteoarticular conditions that are associated with an increased risk of falling. Most frequently, patients with osteoporosis experience either hip or pelvic ring fractures (1). Pelvic ring fractures in the elderly are considered among frailty fractures (2) and are usually encountered in women over the age of 80. The gender-specific incidence has a different pattern according to age - from 0.54/0.38 ‰ for patients aged 65-69 to 9.35/4.45 ‰ for ages over 90; also, inci-

dence is higher for institutionalized or moderately disabled persons (3). Most often, pelvic ring fractures in the elderly are the consequence of a minor injury - either same-level fall at home or during the bed to chair transfer. Frequently, these fractures occur on an osteoporotic bone. Both pre-existing comorbidities and the clinical consequences of the fracture (significant pain, total immobilization, and dependency) darken the prognosis and require a thorough assessment prior to a therapeutic decision (3). There is no consensus regarding the orthopedic approach: surgery versus conservative treatment, both being associated with considerable risks (4, 5).

We present the case of an elderly female patient with multiple pelvic ring fractures, for whom a conservative treatment was recommended. She was subsequently transferred to the Geriatric Clinic of the "Dr. C.I. Parhon" Hospital for a concomitant cardiovascular complication. The comprehensive geriatric assessment and the therapeutic plan, which were managed by a multidisciplinary team, led to the satisfactory recovery of the patient and allowed her to return to her own home.

CASE REPORT

We present the case of an 80 year-old female patient, living in an urban house, who was admitted to the Orthopedics Department with multiple pelvic ring fractures (fracture of the anterior left acetabular wall without displacement, left ischiopubic fracture, sacral wing fracture) following a minor fall injury at home (fig. 1). She had a recent medical history of arterial hypertension (for which she was prescribed treatment with ACE inhibitors) and osteoporosis. During hospitalization, a routine cardiology consultation revealed an episode of tachyarrhythmia (high frequency atrial fibrillation).

Fig. 1. The X-ray of the patient showing multiple pelvic ring fractures (fracture of the anterior left acetabular wall without displacement, left ischiopubic fracture, sacral wing fracture).

Due to the recently-diagnosed cardiovascular comorbidities and because the fractures were stable (no associated displacement), the orthopedic surgeon opted for conservative treatment, despite the fact that the fractures had occurred on a pathologic bone. The patient was transferred to the Geriatric Clinic for a thorough assessment prior to her discharge at home.

On admission, the patient had significant pain in the lumbosacral and pelvic areas, with partial bed immobilization (she could turn from one side to the other), mildly elevated blood pressure, psychomotor agitation, anxiety, and depression. Additional investigations did not identify other medical conditions except for the previously diagnosed arterial hypertension. Comprehensive geriatric assessment revealed: malnutrition (21/30 MNA score), complete dependency (assessed by ADL and IADL scales), moderate depression (assessed by the GDS scale), clinical frailty (assessed by the Freid scale) and the absence of cognitive disorders

(assessed by the MMSE scale). Both a physiotherapist and psychologist consulted the patient and participated in developing the management plan.

The therapeutic approach of the multidisciplinary team focused on the following points: ensuring careful monitoring of the cardiovascular status, providing an appropriate diet for malnutrition, osteoporosis and heart disease, securing an immediate, suitable and continuous functional recovery, offering psychological counseling and qualified care to prevent complications of prolonged bed rest. Special attention was given to functional recovery, due to the complexity of the case. The treatment plan had to take into account the fact that fractures occurred on osteoporotic bones (6), that the orthopedic treatment consisted in relative bed rest (no cast immobilization and no stepping on the affected leg for 60 days), and that the patient wanted to return as soon as possible to her home, where she lived alone.

One of the most important roles was played by the physiotherapist, who had to attempt meeting the following aims:

a. decrease the pain that occurred mainly during the recovery sessions, but also while performing the smallest movements in the bed;

b. recovery, restoration and consolidation of the affected motor functions, correct and full recovery of force and joint mobility, muscle strength recovery in both upper and lower limbs (7);

c. restoration of stability, controlled movement and ability for body support when the patient began to walk using the frame, crutches and, at the end, the cane, with gradual and correct resumption of independent walking;

The procedures used to accomplish the set goals were:

- electro acupuncture at acupoints in the painful area for instant pain relief, resulting in greater amplitude of the movements during passive, active-passive and active physiotherapy;

- sedative and relaxing therapeutic massage, which resulted in a significant decrease of pain. This procedure also had a positive mental effect on the patient, who's compliance during treatment increased; active involvement of the patient augmented the beneficial effects of physiotherapy, with excellent results despite osteoporosis and old age (which, usually, is a hindrance in the recovery dynamic);

- massage and reflexotherapy, which determined a growth in basal metabolic rate, stimulating respiratory and circulatory apparatus functions, improving sleep quality and the person's general state;

- breathing exercises and bilateral posterior chest massages in order to avoid bedsores and, more importantly, to prevent decubitus pneumonia.

Recovery treatment was gradually more complex. As the fracture consolidated, the pelvic member on the fracture's side was loaded progressively and the use of the thoracic limb was encouraged (8). The patient's relative bed rest lasted for 3 weeks as per orthopedic recommendations for stable fractures. At the beginning of the third week, the patient sat up at the side of the bed, and, by the fourth week, she managed standing up and performing short movements (without pressuring the affected limb), with the help of an attendant and the walking frame, which enables good control of body weight distribution and center of gravity adjustment. At the same time, improvement of the nutritional status, decreased anxiety and depression, and

efficient control of blood pressure values were achieved. 60 days after the injury, the patient was discharged with a relative dependency status (walking by cane) and need of in-home help.

DISCUSSIONS

Given the improved life expectancy, the rising incidence of osteoporosis and frailty inevitably led to an increase in pelvic ring fracture rates, which are considered frailty fractures. They typically involve elderly females (over 80 years old), are diagnosed after a minor injury (sometimes the patient does not remember when the trauma occurred) and have disastrous consequences for the patient and their caregivers: prolonged bed rest with severe deterioration of the muscles, joints and bones associated with increased dependency level (in some cases, institutionalization is needed due to the inability to return home). This represents an important health care burden both from a social and an economic point of view (9).

Conservative treatment, which is preferred in the stable fractures of patients with clinical frailty, cardiovascular comorbidities, accelerated osteoporosis and malnutrition is associated with a long period of immobilization and bed rest, and, inevitably, all its complications. The complex treatment (physiotherapy, psychotherapy, proper nutrition and continuous medical monitoring), performed in a specialized medical unit, is the main step towards therapeutic success, allowing complex patient recovery and restoring quality of life.

Because the Romanian health care system lacks specialized centers for complex recovery of the elderly, this program was implemented at the Geriatric Clinic, where constant supervision and medical care, nutritional counseling, psychological assistance and a thorough physiotherapy schedule, together with patient's compliance and her wish to return home, led to the recovery of walking ability, with a significant decrease of the dependency level, and allowed for a quality of life status similar to that prior to the fracture.

CONCLUSION

Pelvic ring fractures in the elderly are considered among frailty fractures because they are usually encountered in women over the age of 80. There is no consensus regarding the orthopedic approach: surgery versus conservative treatment, both being associated with considerable risks. The particularities of old and very old age (frailty and osteoporosis, the tendency to malnutrition, depression and cognitive impairment, the concomitant chronic diseases) need a comprehensive geriatric assessment performed by a multidisciplinary team who is well trained to devise a complex recovery plan, performed in a specialized clinic and which would allow the patient to return, as much as possible, to the way of life that existed prior to fracture.

GINGIVAL, PLASMA AND SALIVARY LEVELS OF MELATONIN IN PERIODONTALLY HEALTHY INDIVIDUALS AND CHRONIC PERIODONTITIS PATIENTS: A PILOT STUDY

Melatonin (N-Acetyl-5-hydroxytryptamine) is an indole amine hormone synthesized predominantly by the pineal gland. Extrapineal synthesis and release of melatonin can occur from organs like ovaries, retina, gastrointestinal tract and also from cells such as human lymphocytes. Melatonin regulates circadian rhythm and the biological clock in the human body. In addition, it performs numerous other functions like immunomodulation and osteopromotion. Melatonin has potent antioxidant action against reactive oxygen species and can mitigate deleterious effects of free radical damage in the human body. It is well known that chronic periodontitis is an inflammatory condition of the tooth supporting structures with a microbial aetiology, in which dysregulated immune response and a jeopardized oxidant - anti oxidant balance play a major role in causing tissue destruction and tooth loss. Previous studies have shown increased oxidative stress markers and lowered antioxidant status in periodontal disease compared to health. In this context, the presence of melatonin as an antioxidant in saliva and plasma and its association with the pathogenesis of chronic periodontitis has been researched. It has been hypothesized that salivary melatonin can act as a potent local antioxidant boosting the defence mechanism against periodontal pathology. Till date no study has investigated, melatonin levels in the gingival tissue. This study demonstrates the presence of melatonin in gingival tissue. Furthermore, melatonin levels are lowered in gingival tissues of chronic periodontitis patients (Balaji TM, Vasanthi HV, Rao SR, et al. Gingival, Plasma and Salivary Levels of Melatonin in Periodontally Healthy Individuals and Chronic Periodontitis Patients: A Pilot Study. Journal of Clinical and Diagnostic Research. 2015, Vol-9(3): 23-25).

PREDISPOSANT FACTORS FOR INTIMAL HYPERPLASIA AND THEIR MECHANISMS OF ACTION IN OPEN VASCULAR SURGERY. A REVIEW (Abstract): **Background:** Intimal hyperplasia is a multifactorial process that determines local stenosis and subsequent ischemia after revascularisation procedures. It is controlled by a plethora of cytokines, growth factors and proteases that interact through multiple mechanisms, empowering or inhibiting their hyperplasic action. Although the elements involved are the same, the resulted degree of vascular stenosis varies. **Methods:** To highlight the predisposing conditions which enhance the vascular response to injury we consulted articles from Pubmed database, searching for the keywords "intimal hyperplasia", "neointimal hyperplasia" and "risk factor". **Results:** 101 articles were included in the study. Risk factors analyzed are classified into local and systemic and the mechanisms by which they augment the process are explained. **Conclusion:** Knowledge of risk factors and their control when possible is a key element in increasing revascularization patency. **Keywords:** VASCULAR INJURY; INTIMAL HYPERPLASIA; RISK FACTORS.

Intimal hyperplasia, a process triggered by vascular injury, is the proliferation of vascular smooth muscle cells in the media, followed by their migration to the intima, the transformation from contractile in secretory phenotype and secretion of extracellular matrix constituents, end result being a narrowing of the vascular lumen and subsequent ischemia in the irrigated territory (1). The process is controlled by a plethora of cytokines, growth factors and proteases that interact through multiple mechanisms, empowering or inhibiting their hyperplasic action (1). Although the elements involved are the same, the resulted degree of vascular stenosis varies. This raises the question whether there are predisposing conditions which is thought to enhance the vascular response to injury and can be controlled in order to increase revascularization patency.

METHOD

Consulting articles from the Pubmed database, we conducted a search for the combination of keywords "intimal hyperplasia" AND "risk factor", “neointimal hyperplasia” AND "risk factor", until september 2014. The search yielded 430 articles. The two authors individually screened the abstracts and 101 were found relevant for this study. From this articles, the fol-

lowing variables were colected: paper first author, year of publication, risk factor described, and method of determination (animal experiments, clinical trials).

RESULTS

Although there is a great heterogeneity of the determined risk factors, for a better understanding we decided to classify into local and systemic factors. For every risk factor both experimental and clinical trials results are reviewed and a short description of the mecanism involved is provided.

LOCAL FACTORS

Local hemodynamic factors have a major influence on vascular remodeling process. A basic conditions for an increased patency in arterial revascularization is the existence of a quality runoff. Christoph Hehrlein conducted an experiment on dogs, ligating the femoral artery proximal to its trifurcation and thus altering runoff and then producing laser thermal injury and balloon endothelial denudation. He found an average increase of 32% of the area of intimal hyperplasia in animals with altered runoff compared to control, $p < 0.01$ (2), independently of the severity of the lesion. The trend of development of neointimal tissue in conditions of poor runoff was explained by Dobrin. The author has quantified the effect of each force acting on the vascular wall in subsequent histological changes and found that intimal hyperplasia occurs under low shear stress conditions (3). Shear stress is directly proportional to the speed of blood flow, which in turn is directly influenced by the runoff. Bassiouny showed that at the level of an end-to-side anastomosis there are two areas of intimal hyperplasia: at the suture line and at the receiving vessel floor. Realizing an artificial model which simulated the conditions of geometry and pulsatility of an end-to-side anastomosis, he showed that at the floor level there is an area of stagnant flow compared to the cuff, where the flow rate is high and it correlates with the lack of cuff hyperplasia experimentally demonstrated (4). Another way in which an altered runoff promote intimal hyperplasia is due to a low local concentration of vasodilator endothelium released factors (NO, prostacyclin). As Rubanyi proved, the release of this factors is directly proportional to the flow rate (5). These substances have a powerful antimitogenic effect. Under conditions of poor runoff, their low concentration allows the unduly development of neointimal tissue. In this regard, Morinaga showed that intimal hyperplasia areas shrinks if the vessel is reimplanted into a normal flow parameters system (6). All of this experimental studies were confirmed by clinical trials. In a series of 191 femoropopliteal and femorodistal reconstruction, it was determined that the rate of patency at 6 months dropped from 88.2% in patients with good runoff to 21.8% in those with altered runoff ($p<0.01$) (7). Scali shown that a low distal graft end-diastolic velocity determined by duplex ultrasound at the end of the procedure predicted poor outcome in terms of patency (8).

Characteristics of autologous grafts.

Vein grafts used for myocardial and peripheral revascularization often show areas with altered histological structure, either **fibrous or varicose**. Histological studies showed in these areas a severe medial disruption, with smooth muscle cells transformation from contractile to secretory phenotype, an increase in the number of vasa vasorum and altered extracellular matrix metabolism (9). Transplantation of

venous grafts in the arterial circulation submit them to a tensile and shear stress much higher than those normally acting on the vein wall. Normal physiological response to the augmentation of these forces is the process of "arterialisation", characterized by panmural hypertrophy, both cellular and matrix (9). This process is triggered by endothelial denudation caused by shear stress and muscle cell proliferation and subsequent apoptosis caused by tensile stress (10). Both in stenotic and varicose dilated areas laminar flow is affected, there are major turbulence and tangential deformation which causes major endothelial and medial damage (11). These lesions, appeared on a vascular wall with altered histological structure, have the effect of an exacerbated intimal and medial hyperplasia. It was shown experimentally that external stenting of venous grafts resulted in uniform flow, attenuation of tangential distension and limited intimal proliferative response (12). This procedure was adopted in clinical practice. A randomized trial of external stenting for saphenous vein grafts in coronary artery bypass grafting found that mean intimal hyperplasia area was significantly reduced in the stented group versus nonstented group and determined marginally significant improvement in lumen uniformity and less ectasia in the stented group (13).

Vascular trauma occurred during the process of harvesting the graft is another factor contributing to the development of neointima. It has two components. First, the dilatation has the effect of physical trauma - endothelial denudation. In these areas there is adherence of platelets and leukocytes that release cytokines and growth factors (14). Bare areas are endotelized in the first 14 days by proliferation and migration of adjacent endothelial cells (15), but the result is a dysfunctional neoendotelium, with a low capacity in production and secretion of nitric oxide and prostacyclin which are antihyperplasic factors (16). The second component is the ischemic trauma, related to the time elapsed until reimplantation. It should be noted that oxygen used by endothelial cells and the internal media comes through diffusion from the bloodstream, while external media and adventitia are oxygenated by vasa vasorum network. Initially, after harvest, the graft undergo a panmural ischemia, being affected all three tunics. Once inserted into circulation, endothelium and internal media resume their aerobic metabolism, whereas ischemia persists in external media and adventitia until the completion of vasa vasorum neovascularization. Ischemic injury promote intimal hyperplasia in two ways. Superoxide radicals synthesized in anaerobic metabolism (17) has a potent mitogenic effect (18). Second, it has been demonstrated a trend of migration of smooth muscle cells from the external media to intima, due to higher oxygen concentration at this level, regardless of the presence of endothelial injury when vasa vasorum are damaged (19).

SYSTEMIC FACTORS

Metabolic alterations.

As in the case of atherosclerosis, **diabetes** plays an important role in neointimal proliferation. The augmented rate of coronary stenosis after angioplasty and stenting in diabetic patients compared to nondiabetics, having as substrate intimal hyperplasia, has been documented in several studies (20,21). Transient hyperinsulinaemia appears to be the main cause and occur both in patients treated with oral anti-diabetic drugs

who have insulin resistance as well in patients receiving intermittent subcutaneous insulin (22). Insulin stimulates intimal hyperplasia by accelerating the production of growth factors and by direct mitogenic effect (23). The second cause is represented by the advanced glycation end products (AGEs), which accumulate in vascular tissue with age (24). The vascular smooth muscle cells have specific receptors (RAGE) for them and the AGE - RAGE interaction results in stimulation of inflammation, smooth muscle cell proliferation and increased secretion of extracellular matrix components (25). In a murine model, insulin-resistant Zucker fatty rats who recived long acting insuline theraphy for 4 weeks, carotid intima/media ratio was significantly reduced after balloon catheter injury compared to control (26). A study performed on 14,788 patients who underwent infrainguinal lower extremity arterial bypasses found that diabetes mellitus had a negative association with early graft failure (95% confidence interval, 0.58-0.89, p=0.002), determined by intimal hyperplasia and not by progression of atherosclerosis (27).

Additive effect of **hypercholesterolemia** in the development of postlesional intimal hyperplasia is known since 20 years ago and is based on exacerbating local inflammatory process (28). Under conditions of hypercholesterolemia, monocyte chemoattractant protein (MCP-1), also known as chemokine ligand 2 (CCL2) is expressed on vascular smooth muscle cells in large numbers (29) and its receptor (CCR2) on the surface of monocytes. CCL2-CCR2 interaction is the main way by which monocytes are recruited in increased number at the site of an endothelial injury (30), maintaining the inflammatory process and stimulating the development of neointimal tissue. The inhibition of this interaction by administration of CCL2 monoclonal antibodies has resulted in a marked reduction in neointimal area (31). In animal experiments it was found that under hypercholesterolemia, there is a growing mRNA expression of type I collagen, increased secretion of this type of collagen in the extracellular matrix, together with a significant reduction of matrix metalloprotease activity (32). A third negative effect induced by hypercholesterolemia, closely linked to oxidative stress, is the slowdown in postlesional reendotelisation process (33). In a study on patients with carotid restenosis after endarterectomy, it was found that levels of plasma cholesterol, total triglycerides and low density lipoprotein apoprotein B were higher than control (34).

Homocysteine. One of the first studies that have shown a link between increased blood levels of homocysteine and postendarterectomy progression of carotid intimal hyperplasia was carried out on a animal model by Frederick Southern in 1998 (35). Since then, many of the mechanisms by which hyperhomocysteinemia causes vascular injury and promotes neointimal formation were elucidated and are represented by chronic inflammation and subsequent endothelial damage, modulation of gene expression by altering methylation, inducing a procoagulant status, induction of apoptosis and extracellular matrix remodeling (36). The posibility of hyperhomocysteinaemia beeing a risk factor for vein grafts stenosis was examinated in a case-control study, that revealed a direct connection between elevated plasma levels of homocysteine and low patency rates (37).

Coagulation disorders.

Malfunctions of elements involved in the coagulation process can result in aug-

mented vascular hyperplasia. Platelet adhesion to vascular lesion and parietal thrombus formation are the triggers for the vascular healing process. It is known the role of platelets in the process, mainly through PDGF release, the most powerful mitogen for cells of mesenchymal origin and a potent chemoattractant for smooth muscle cells, macrophages and neutrophils (38). An exacerbated response to injury when the platelet count is pathological increase was documented in chronic myeloproliferative disorders, especially polycythemia vera and essential thrombocythemia and is manifested both in the medium vessels - the coronary and pedal arteries (39) and the smaller vessels - arteries dermis, causing generalized racemose livedo (40).

Factor Xa forms a complex with factor Va and cleaves prothrombin to active thrombin, which converts fibrinogen to fibrin (41). Thrombin also stimulates platelet aggregation and degranulation by cleaving protease activated receptors on the platelet membrane. It is a powerful smooth muscle cells mitogen and promotes their migration in the intima (42). Increased thrombin generation conditions, like neoplasic diseases, prothrombin thrombophilia or postmenopausal hormone replacement therapy were associated with an accelerated intimal hyperplastic response (43,44). Procoagulant activity of thrombin is specifically inhibited by antithrombin III in plasma and heparin cofactor II (HCII) in the subendothelial layer of the vascular wall, in the presence of dermatan sulfate. Because heparin cofactor II / dermatan sulfate complex effectively inactivates surface-bound thrombin, it inhibit proliferation of vascular smooth muscle cells and fibroblasts. A genetic deficiency of this factor is highly associated with an exacerbated response to injury (45). Takamori demonstrated on a group of 134 patients that a high HCII plasma level is a protective factor against in-stent restenosis (46).

Hyperplasia is also promoted when there is an increase in fibrinolysis. Plasmin is formed from plasminogen under the action of a series of activators (PA), most important being urokinase type – PA (u-PA) in the serum and tissue type – PA (t-PA) bound to fibrin (47). The role of plasmin is to remove the cloth by degrading fibrin, but it promotes hyperplasia by mediating the migration of smooth muscle and inflammatory cells within the blood vessel wall, increasing collagen deposition and cholesterol accumulation (48). Plasminogen activator inhibitor type 1 (PAI-1), a protein synthesized by vascular endothelial and smooth muscle cells, is the primary inhibitor of t-PA and urokinase (49). Although increased levels of this inhibitor correlates with myocardial infarction (50), decreased plasma levels of PAI-1 is documented to be a risk factor for stent restenosis (51) and experimental animal models have shown to reduce the area of hyperplasia when the production of this protein is stimulated (52). These apparently paradoxical results have a common denominator, namely reduced production of plasmin. A low level of plasmin prevent fibrinolysis, thus promoting clot progression, but also this low level involves a decreased prohiperplastic effect.

Cigarette smoking

Known as the main risk factor in the progression of atherosclerosis, smoking plays an important role in initiating and augmenting intimal hyperplasia. Exposure to cigarette smoke increases the number of platelets and their ability to adhere to damaged vessel wall and inhibit their mito-

chondrial activity (53). Smoking also cause neutrophilia and the activation of neutrophils by the complement system. Although neutrophils do not secrete growth factors, they contribute to tissue injury through the release of oxygen radicals and proteases (54). Chronic cigarette smoking increases monocyte adherence to cultured human umbilical vein endothelial cells in vitro, promoting inflammation (55). Endothelial cells are also affected, smoking disrupting normal regulatory properties, increasing cell wall permeability and the likelihood of detachment with injury and decreasing endothelial cell DNA synthesis . The smooth muscle cells are direct affected by cigarettes via polycyclic aromatic hydrocarbons found in the smoke, which are increasing their proliferation rate and viability (56). Experiments performed on murine models had shown that smoking accelerates intimal hyperplasia in a dose-dependent manner (57).

Endothelial progenitor cells

The vascular endothelium is a dynamic organ, formed by a continuous layer of cells that cover the luminal surface of blood vessels and react to physical forces and chemical signals, affecting vasomotion, thrombosis, platelet aggregation and inflammation. Endothelial progenitor cells (EPCs) isolated from peripheral blood are originating from the bone marrow. Their role is to migrate, differentiate into endothelial cells and cover intimal defects (58). It has been demonstrated a direct correlation between the decreased number of EPCs in peripheral blood and progression of coronary artery disease (59). Likewise, in laboratory experiments, autologous EPCs transplantation enhanced the vasculoprotective properties of the reconstituted endothelium resulting in inhibition of neointimal formation (60). Another study showed that anti - vascular endothelial cadherin antibody-coated stents captured circulating EPCs, thus resulting an accelerated endothelial recovery on stent and reduced intimal hyperplasia (61). The number of circulating EPCs falls in patients with hypercholesterolemia, vitamin D deficit, low plasma estrogen level and is stimulated by exercise training, administration of erythropoietin and statins.

Discussion

Although the progression of atherosclerosis in some cases is causing stenosis after open surgical revascularization, most frequently the low patency of these procedures is due to a compounded vascular healing process after injury. Therefore the vascular surgeon must know the intimate mechanisms by which the process unfolds and especially the causes that exacerbate it. The most important contribution that the doctor can have in limiting the negative effects caused by hyperplasia is represented by run-off selection, when this option exists. Whether it is coronary or peripheral revascularization, a poor run-off have catastrophic effects on intervention patency. For infragenicular bypasses, American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines recommend that the tibial or pedal artery that is capable of providing continuous and uncompromised outflow to the foot should be used as the site of distal anastomosis (62). This recommendation points out the importance of the outflow artery status throughout its length on limb salvage, patency and pacient survival. There are also numerous angiographic scores that quantify the quality of runoff, the most used being Rutherford revised score, a method validated by clinical stud-

ies to predict the evolution of revascularization in patients with critical limb ischemia (63).

Vein graft harvesting, preparation and ischemia time also influence the degree of progression of intimal hyperplasia. Increasingly more surgeons are using the „no touch" technique in venous graft preparation. This procedure involves that the vein is neither stripped nor distended, but harvested with a fat pedicle. The PATENT study compared markers of vascular injury and smooth muscle cells activation in veins harvested using this technique vs the conventional one and found that „no touch" preserved intimal, medial and adventitial architecture, with similar leg recovery in both groups. (64). Distention during preparation is an important element in future graft evolution. A distention pressure lower than 140 mmHg prevents endothelial denudation, reduction of endothelial-dependent relaxation and intimal thickening and limiting intraluminal pressure can be obtained by using a pressure release valve (65). Preparing the arteries before vein harvesting and making the anastomoses simultaneously by two teams of surgeons decreases graft hipoxia, simple gestures with a huge impact on long term patency. Many vascular surgeons refuse to use varicose veins in arterial reconstructions, preferring synthetic materials, but new external scaffolding technologies are emerging with encouraging results, especially in coronary surgery. External stenting stabilizes flow parameters, particularly shear stress, downregulating the molecular processes involved in neointimal formation (66).

Although local factors outweigh the process, should not be forgotten the importance of systemic factors, which are most often controllable. The antidiabetic and lipid-lowering medication should be carefully determined and adjusted by the diabetologist prior to surgery and a close collaboration between the vascular surgeon and the haematologist is necessary in patients with myeloproliferative disease requiring revascularization procedures. New evidences emerge in favor of short-term dietary restriction immediately before surgery to reduce intimal hyperplasia and to protect from ischemia-reperfusion injury (67). Also, animal studies and in vitro experiments suggests that a short anti-inflammatory treatement with dexamethasone decreases vein graft thickening and levels of proinflammatory cytokines associated with hypercholesterolemia, but there is a lack of bed-side evidence (68). The beneficial effect of smoking cessation on reducing neointimal formation has been proven by numerous studies, so the patient should be directed to specialized antismoking centers prior to surgery. One study showed that stopping smoking rapidly increases circulating levels of endothelial progenitor cells and the magnitude of increase was greater in light smokers than in heavy smokers (69). Another study determined that heavy smoking before surgery significantly increase matrix metalloproteinase subtypes MMP-2 and MMP-9 gene expression, in the same time decreasing the gene expression of tissue inhibitors of metalloproteinases TIMP-1 and TIMP-2 (70).

All these therapeutic measures conducted at the right time can significantly increase the patency of revascularization procedures.

CONCLUSIONS

Intimal hyperplasia is a multifactorial process that determines local stenosis and subsequent ischemia. In addition to drugs

that have proven useful in inhibiting the process, knowledge of risk factors and their control when possible is a key element in increasing revascularization patency.

OXIDATIVE STRESS IMPLICATIONS IN VARIOUS LUNG DISEASES. FOCUSING ON ONE LUNG VENTILATION (Abstract): One the most intriguing biomedical fact nowadays is that many of the existent diseases exhibit a certain molecular component expressed through oxidative damage. In this way, it seems also that lung diseases have an oxidative stress component which is clearly shown by impairment in oxidant/antioxidant mechanisms balance. In several pathological cases, each and every cell present in lung tissue may be capable to produce reactive oxygen species (ROS) as a part of the inflammation signaling. ROS are also produced in normal conditions, but a strong antioxidant defence system acts in order to transfer the impaired electrons of the ROS reducing them to neutral species. In this way, in one lung ventilation (OLV) surgical maneuver an increase in the ROS production occurs mainly due to 100% use of oxygen during artificial ventilation. Unfortunately, the only way in which the oxidative damage can be minimized is by carefully and correctly executing this maneuver. Moreover, no antioxidant therapy can be considered working or safe yet, although some animal modeling showed promising results. **Keywords**: REACTIVE OXYGEN SPECIES, THORACIC SURGERY, LUNG RESECTION, COMPLICATIONS, ANTIOXIDANT THERAPY.

Nowadays, it is generally known that living organisms on Earth can survive only due an appropriate concentration of oxygen in the breathing air. Both plants and animals' metabolic pathways are based on a continuing exchange of atomic particles between reactive species and pathway partners. At the same time, it seems that these reactive species also play an important part in the process that make living bodies age and finally die. As the oxygen species formed in respiration chain participate in all homeostatic reactions, energy production, enzymatic activation, pathways regulation and so on, it seems that the same species can also easily participate in order to end cellular activity by activating the well-known self-destructive mechanism called apoptosis. This paradox can be well observed in lung diseases (LD) where the oxygen privation leads to serious tissue damage (1). It was only currently that we understood that reactive oxygen species (ROS) can also play a crucial role in LD and that the lung tissue may be extremely vulnerable when exposed to oxidative

stress during a LD, a surgical procedure, or after specific post-operatory maneuvers such as lung-ventilation. Therefore it seems that oxidative stress damage may be of great importance when it comes on LD due to lung vulnerability to the toxic effects of oxygen and the oxygen damage can occur and radically change pathologies features.

The pathology of oxidative stress begins when an imbalance in oxidant-antioxidant systems occurs. The accumulation of ROS can cause damage to DNA, lipids, proteins, and carbohydrates. There are methods to measure oxidative stress shown for example by increased lipid peroxidation products, or the DNA oxidation, and protein carbonyl formation in lung tissue. As the lipid peroxidation can be an excessive ROS production marker, the oxidized lipids may possess signaling potential. It is the case of the isoprostanes, by-products of membrane lipid peroxidation involved in bronchoconstriction occurrence and airway hyperresponsiveness in asthma that can also be powerful vasoconstrictors in pulmonary arterial hypertension or acute lung injury (2, 3).

One lung ventilation (OLV) is currently used in video-assisted surgery and also in open lung surgery. OLV purpose is to decrease the blood flow through pulmonary circulation that could lead to temporary ischemia followed by reperfusion after restoring ventilation, in combination with iatrogenic hyperinflation, all of which can imply in ROS production (4).

It is interesting that both common lung diseases and artificial lung ventilation involve oxidative stress damage to lung tissue, but no comparative or cumulative study was made. This review aims to present several aspects considering the oxidative stress occurring generally in the common lung diseases and particularly during or after surgeries that require the assistance of artificial lung ventilation. Surprisingly, it seems that even a surgery tool may mimic or increase oxidative stress leading eventually to lung tissue damage.

OXIDATIVE STRESS MECHANISMS IN LUNG DISEASES

Many studies show that endogenous oxidative-antioxidative mechanisms may be critical in LD (as reviewed by - 5). As the reactive species of oxygen and nitrogen are ubiquitous in nature, they must be produced by both endogenous and exogenous sources. Endogenous sources may be the cellular organelles responsible for respiratory chain and hydrogen peroxide metabolism (6, 7). In other words, when the unpaired electrons from the mitochondrial transport chain occur during oxidative phosphorylation, they are reduced by the molecular oxygen which leads to superoxide production which easily changes into hydrogen peroxide. This is the time when the peroxisomes are activated and their enzymes contribute to the catalysis of these reactive oxygen species (ROS), but being an enormous source of oxidative stress (8-10).

Studies show that there are many important cellular enzymes that are implicated in lung diseases pathologies (11-14). NADPH oxigenase, cytochrome P_{450}, lipooxygenases may be just some of these enzymes that are produced by various cells in the lung tissue alongside ROS and other molecules.

In this way, neutrophils use to produce a significant ROS concentration due to their antibacterial activity. Therefore, it is in their membrane where the NADPH oxidase generates superoxide which further

activates the reaction cascade in phagocytosis. Alongside the NAPDH oxidase, the myeloperoxidase also is involved in the phagocytosis oxidative reactions mainly producing an extremely reactive Chloride species, the hypochlorous acid (15, 16). However, it has been known that the neutrophils are very few in lung tissues having an extreme mobility during inflammation from the circulation into the lung tissue. Also attracted by the chemical signal of inflammation, the peripheral monocytes may produce significant damage in lung tissue due to their impressive capacity of producing large amounts of superoxide leading to acute injuries (17). In the same way as neutrophils, the alveolar macrophages and eosinophils act like potent ROS producers through the NADPH oxidase activity (18), but the first being active also in physiologic conditions (19) and the latter mostly in allergies or infections (20). Eosinophils also possess peroxidase potential, surprisingly similar to myeloperoxidase.

Endothelial cells, on the other hand, are known to produce ROS in pathological conditions, also being of a great number in lung tissue. Oxidative stress occurs due to these cells during and after hypoxia (21) and in some cases during inflammation (22, 23). They mainly produce superoxide, sent by membrane channels to extracellular compartments of lung tissues, and hydroxyl radicals (24). Smooth muscle cells can also produce ROS through NADPH-like oxidase complexes and may produce airway hyperactivity (25, 26).

Pneumocytes in the alveolar epithelia and lung fibroblasts also possess intense metabolisms being involved in inflammation and tissue reconstruction. Type II pneumocytes may be precursor for type I therefore in the differentiation process a certain oxidative stress occurs (27, 28). Lung fibroblasts are attracted by inflammation signals (such as cytokines) and produce ROS intracellularly and extracellularly (29).

Therefore it seems that each type of cells present in the lung tissue may actually generate ROS, either in physiologic or pathologic conditions. It is not yet sufficiently clear whether if an imbalance in the cellular system of ROS formation and degradation act as a clean pathological trigger. Extremely important should be the fact that most of the ROS play important roles in signalling processes of several survival pathways such as apoptosis.

ROS production from exogenous sources may also play an important role in LD. Environmental toxins or diet could also promote the onset of LD. Classical examples may be the exposure to different herbicides or pesticides that could lead to lung injuries in human by increasing inflammatory factors expression and mitochondrial dysfunction. Also the ethanol poisoning has been shown to lead to lung diseases (30-32) and even ROS-induced cysteine modification in the lungs (33). Even the well-known anti oxidative factors found in the usual diet can influence the inflammatory processes leading to unwanted side effects (34). Other examples may include oxidative stress induction by environmental toxins (arsenic, asbestos, and tobacco) that disrupt the cytochrome P_{450} metabolism (35). All of these changes affect the pulmonary inflammatory response and can finally contribute to lung cancer onset (36-38).

In addition, ROS have been suggested to have a major influence on the rate of postoperatory complications after thoracic surgeries assisted by two-lung ventilation

or one-lung ventilation. It seems that lipid peroxidation may be involved in the atrial fibrillation, a common complication following pulmonary resections (39). Due to high reactive properties, changes in impaired electrons oxygen molecules may be rather difficult to assess, although it might be more suitable to evaluate the ROS production by evaluating the changes that they may lead to different molecules such as proteins. For example, an increase in carbonyl groups may be the result of the increase of hydroxyl radicals which generate protein dimerization following ammonium radical oxidation. Covalent binding of cysteine or methionine protein residues may be associated with excessive oxidation of sulfhydryl groups.

In OLV, it is highly possible that due to the 100% use of oxygen, several changes in oxidative mechanisms occur. As one of the lungs is inactive, the other one must take over the entire activity so that it must provide the entire body the oxygen it needs. In this way, a higher concentration of oxygen must pass through the lung and reach blood. Therefore, it has been shown that higher myeloperoxidase and lower SOD activities may act together in common lung injury caused by hyperoxia due to protein carbonyls formation and high cytokines signalling (40). In the same way, when switching from two-lung to one-lung ventilation, a shunt fraction increases, and oxygenation is impaired. In this way, hypoxemia during OLV may be predicted measuring lung function and distribution of perfusion (41).

ANTIOXIDANT DEFENCE MECHANISMS

While the lung is directly exposed to the environmental oxygen, antioxidant defence is very important (42). Antioxidant defence exists as biochemical systems that help the cells or tissues to restore the proper oxidative balance in order to maintain cellular homeostasis. Obviously, a great part of this defence consists of enzymatic complexes aiming to catalyse the reduction of ROS into low reactive species such as water or to transfer their active potential to other biological important molecules such as NADP(H). The first enzyme in the defence is the superoxide dismutase (SOD) which transforms superoxide in oxygen and hydrogen peroxide. SOD is active both in intracellular and extracellular space with not clear role in antioxidant mechanisms but efficiently decreasing lipid peroxidation and membrane damage (43). As the hydrogen peroxide is produced, the catalase (CAT) and glutathione systems (GS) have the purpose of reducing it to water and oxygen. In spite of SOD, CAT is only active intracellularly (in peroxisomes) alongside the reduced form of glutathione (GSH) (44, 45). Due to the fact that reduction potential of GS bases on the ratio between the oxidized and reduced (GSH) forms of glutathione, and adding that GSH concentration in the alveolar lavage fluid is 100 fold higher than in plasma (44), it seems that GS is a highly active antioxidant system in lung tissues.

Moreover, there are other enzymatic systems that may play direct or indirect roles in the defence against oxidative stress. Among these lie the peroxiredoxins which can reduce hydrogen peroxides, or the thioredoxins which reduce sulfhydryl bonds and they are all implicated in a whole tableau of mutual cellular effort to counteract the damaging effects of normally produced ROS.

Besides the important enzymes that re-

duce the ROS and lipid peroxides such as thioredoxins and GS which in fact were shown to be involved in LD as important protective factors (46, 47), there are also some non-enzymatic endogenous or exogenous antioxidants that can also protect the lung tissue against the peroxidation radicals (48-50). These non-enzymatic antioxidants are mainly "scavengers" of free radicals, such as vitamin C (51), vitamin E (inhibits oxidation of membrane lipids) (52), uric acid (efficient scavenger of peroxynitrite, present in plasma and airway lining fluid) (53), albumin, bilirubin, glutathione or N-acetylcysteine (NAC).

For example, NAC is a potent drug currently used in LD therapies due its potential of directly reacting with ROS and also serving as GSH precursor (50). In this way, it can prevent oxidative stress produced by neutrophil accumulation (54). Many other antioxidant molecules have been studied in LD therapy (55, 56), but currently most of the attention is channeled through enhancing SOD activity (3, 57). Some of these agents reached the clinical trial level, but unfortunately only at a small scale and none of them have yet become commonly used in practice.

PERSPECTIVES IN ANTIOXIDANT THERAPIES

In contrast to the shown fact that the oxidative stress is an important factor in LD, many studies show that the antioxidant therapeutic approach is a matter of efficiency. It seems that many of the trials failed to succeed due to a great number of reasons.

Many of the reasons generally address to the clinical practice such as dosage, delivery and timing. For example, it is known that in active lung injury burst of oxidative stress in a dynamic activity may occur, therefore it is important to calculate the exact amount of antioxidants which must be delivered in order to surpass the oxidative burst but also to be relatively low in order not to impair the oxidant/antioxidant balance in case of an excess. More than that, it seems that the true challenge is the short half-life of the antioxidants in the tissue delivery context being the case of recombinant SOD enzymes (58, 59) which must quickly reach lung tissue through blood stream, a rather problematic matter. In addition, an efficient delivery should be perfectly timed in order that the antioxidant to reach destination than the irreversible tissue damage occurs.

Another important aspect is that ROS may exhibit more than the damaging role of which therapy is addressed to. There might be several interferences of the treatment with the physiological mechanisms. In this way, the immunological response through phagocytosis may be slowed in the case of an antioxidant treatment of airway inflammation, and therefore lung injury (60, 61). Surprisingly, it seems that several studies in 1996 showed that antioxidant therapy may actually increase lung cancer risk due to cell growth promotion potential (62-64). Moreover, an animal model study in 2014 also claims that antioxidant accelerates lung cancer development (65).

Therefore, a more attentive approach should be considered in antioxidant therapies in terms of genetic variation, and regulation of enzymes. There are many genetic variations including polymorphisms and mutations described for many of the antioxidant defence enzymes. For example, in chronic obstruction pulmonary disease, polymorphisms in antioxidant genes related to GS function and all isoforms of SOD

alter the susceptibility to this disease and also the impact on the disease progression (66, 67). Genetic variations in antioxidant enzymes have also been implicated in susceptibility to asthma (68) and acute lung injury. Their importance is crucial because allows the clinicians to target vulnerability rather than the disease itself meaning that a therapy to prevent would be more efficient than a therapy to cure.

CONCLUSIONS

Oxidative damage may be extremely dangerous in terms of lung functions impairment due to their key role in oxygen supplying for the entire body. Many of the lung diseases access the oxidative pathways causing an excess of ROS both intracellular and extracellular in the lung tissue. One-lung ventilation, a common maneuver during thoracic surgery, has also an oxidant component in which, due to the 100% use of oxygen by one lung, the balance between ROS and antioxidant mechanism is impaired. This maneuver must be carefully handled and controlled because most of the after surgery complications occur based on the mechanisms triggered by the excessively produced ROS. Unfortunately, no direct treatment for after-OLV complications is yet available and no antioxidant treatment or preventive therapy can be developed in the absence of a extreme care in assessing OLV maneuver.

MONITORING OF RECURRENCE IN PATIENTS RADICALLY OPERATED FOR PANCREATIC CANCER (Abstract): Pancreatic cancer is a diagnosis that carries a poor prognosis. It is the fourth leading cause of cancer death in Europe and the United States, despite advances in operative technique and postoperative management. Furthermore, there is no consensus on the optimal follow-up schedule of patients after surgery for pancreatic cancer, all recommendations on surveillance being based on low level evidence or no evidence and the leading societies propose different guidelines. As a consequence, follow-up strategies may differ between hospitals depending on preference of physicians. The vast majority of patients develop recurrence within 2 years after surgery, suggesting the necessity of a more intensive follow-up the first 2 years after surgery. It usually occurs after surgery as migratory metastases along major upper abdominal arteries and veins to the liver or peritoneum (70%) and less commonly as loco regional disease as masses closely applied to the surgical margins in the neck or body of the pancreas (30%). Currently, there are no effective means to prevent pancreatic cancer recurrence, despite the fact that it is responsible for the majority of postoperative deaths. **Keywords**: PANCREATIC CANCER, FOLLOW UP, RECURRENCE, SURGERY.

DEFINITION/CLASSIFICATION OF RECURRENCE

Local recurrence has been defined as any failure in the retroperitoneum around the superior mesenteric and celiac arteries, including the tumor bed, remnant pancreas, hepatic hilum, or its regional nodes. It is usually associated with cancer infiltration of the nerves, lymphatic vessels, and connective soft tissues to various extents.

In a study on 27 autopsied patients who underwent potentially curative resection of pancreatic cancer between September 1986 and January 2004, Hishinuma et al. have classified the patterns of recurrence as follow: local recurrence, liver metastasis, peritoneal dissemination, para-aortic lymph node metastasis, distant metastasis (not including hepatic metastasis, peritoneal dissemination, and para-aortic lymph node

metastasis). Anyway, of all of these, the two major patterns of recurrence following the curative resection of pancreatic cancer are local recurrence and liver metastasis.

Most studies have assessed the recurrence patterns of resected pancreatic cancer focusing on diagnostic imaging, but this is not considered sufficient, without performing biopsy and obtaining a pathologically proven diagnostic or based on autopsy findings. In some cases recurrence occurs as an infiltrating tissue, without being a tumor mass, so it is not suitable to be detected by the actual imaging methods (1).

Sites of local recurrence after surgery depend mainly on the original tumor site within the pancreas and the lymphatic drainage routes. Because as a result of adjuvant therapy local inflammatory changes cannot be differentiated from recurrent tumor, close follow-up with serial imaging comparing every study with an initial baseline postoperative examination when available is essential (2).

Niedergethmann et al. have classified the site of recurrence as: local, hepatic, peritoneal, lung or other distant recurrences being assessed by ultrasonography, computed tomography, or biopsy during palliative surgery (3).

One of the most challenging features of pancreatic cancer therapy is the poor outcome and almost invariable tumor relapse even after curatively intended resection. This high rate of relapse is likely due to undetected cancer cells in lymphatic and neuronal tissue. Consequently, microscopic dissemination of cancer cells from the primary tumor is likely either to be present before resection or is the result of the resection itself. Failure of pancreatic resection is often due to loco-regional recurrence or development of distant metastases and peritoneal carcinomatosis by cells that have been seeded before or at the time of surgery. Sperti et al. found that of 78 patients who died after undergoing curative resection, local recurrence developed in 72 %, hepatic metastases developed in 62 %, and 97 % had one or the other. Other studies on patterns of recurrence show that the liver is the most common site of failure after pancreatic resection, but in other studies approximately 75 % of patients who die from pancreatic cancer are found to have a local recurrence in the pancreatic bed. Also, there are reports of 50% local recurrence among long-term survivors, and despite adjuvant treatment (4).

Recurrence can be defined as reappearance of tumor tissue after intended curative resection of pancreatic cancer. We are proposing a classification into local recurrence, regional and distant metastases.

Local recurrence is considered to be situated in the retroperitoneum around the superior mesenteric and celiac arteries, including the tumor bed, pancreatic remnant, hepatic hilum.

Regional recurrences include the regional lymph nodes: hepatic hilum, para aortic lymph nodes or any other group in the region.

Distant metastases can be classified into intra abdominal (liver, peritoneal) and extra-abdominal (lung).

PROGNOSTIC/PREDICTIVE FACTORS OF RECURRENCE

Due to the lack of sensitive and specific methods to diagnose pancreatic cancer or the recurrence after intended curative surgery, many efforts have been made to find predictive factors of recurrence of tumor tissue.

Prognostic factors in patients with pancreatic carcinoma have been analyzed based on survival but not on recurrence in

the majority of previously published large series reports.

Shimada et al. retrospectively examined recurrence patterns within a year and predictive factors associated with early recurrence in 133 patients who underwent macroscopic curative pancreatectomy with extended lymphadenectomy for invasive pancreatic carcinoma. More than 80% of the early recurrences were found to be distant and the liver accounted for 46%. Loco-regional recurrence was recognized in only 9% of patients, a lower rate than in previous reports (5, 6).

These findings suggest that microscopic metastases already existed in the liver, peritoneal, or other distant organs at the time of operation. In these patients local cancer control alone could not contribute to long-term survival because the major cause of failure was distant metastases.

Sampling of para-aortic lymph nodes is recommended as a routine examination at laparotomy. When positive nodes are confirmed by frozen section, early recurrence and poor survival are inevitable, even after radical surgery, extended lymphadenectomy included.

This study highlighted that para aortic lymph node metastasis was the definitive predictor of early recurrence and shorter survival (12 months). Based on these results, radical pancreatectomy with extended lymphadenectomy should not be recommended when para-aortic lymph nodal metastasis was confirmed by intraoperative biopsy. Even if there is no apparent hepatic metastasis and peritoneal dissemination after surgical exploration, routine sampling of para aortic nodes for investigation by frozen section is recommended before radical surgery because palpation or intraoperative ultrasound cannot predict para aortic nodal metastases (7).

IMPORTANCE OF SPECIALIZED SURGEONS / HOSPITALS

Among the multiple factors influencing the outcome of patient operated for pancreatic cancer, the grade of surgeons' specialization and hospital volume were taken into the account and therefore analyzed in a few studies.

One complex study regarding these issues has been performed by Sosa et al. under the supervision of Prof. John L. Cameron, at The Johns Hopkins University School of Medicine and published in 1998. They analyzed the hospital discharge data from all non-federal acute care hospitals in Maryland (n = 48), identifying all the patients with pancreatic cancer who underwent a pancreatic resection, palliative procedure, or stent procedure between 1990 and 1995. The hospitals were categorized as high-, medium-, and low-volume providers according to their average annual volume of these procedures. Multivariate regression was used to examine the association between hospital volume and in-hospital mortality rate, length of stay, and hospital charges, after adjusting for differences in case mix and surgeon volume. The result show that increased hospital volume is associated with markedly decreased in-hospital mortality rates and a decreased or similar length of stay for all types of procedures. After adjustment for case mix differences, the relative risk (RR) of in-hospital death after pancreatic resection was 19.3 and 8 at the low- and medium-volume hospitals, respectively, versus the high-volume hospital; after bypasses, the RR of death was 2.7 and 1.9, respectively; and after stents, the RR was 4.3 and 4.8, respectively. So patients with pancreatic cancer who are to be treated with curative or palliative procedures appear to benefit from being operated in high-volume hospi-

tals. These results support previous studies about the better outcomes with greater case volume and also extend the findings of studies that have shown an association between increased hospital volume and better outcomes for pancreatico duodenectomy (8-11).

Improved performance is not associated with patient volume but also with the volume of patients with pancreatic cancer of similar types.

The explanations could reside in the fact that high-volume centers may be able to develop a systematic approach and organizational routines for handling such patients by developing critical pathways and involving case managers which, in turn, may raise the performance of all participants in the health care team.

The data from this study suggest that the combined effect of the whole team of pancreatic cancer care providers at a hospital may be more important than the number of surgeries performed by a particular surgeon. Hospital volume had the strongest and most consistent association with outcomes. A large experienced surgical team, specialized nurses, intensive care specialists, anesthesiologists, radiologists, and hospital monitoring procedures are of big importance for the complex procedures performed in patients with pancreatic cancer (12). Overall, according also to other literature data, patients with pancreatic cancer requiring procedures for their disease may benefit from referral to a high-volume provider, regardless of whether they require curative resection or a palliative bypass or stent and help to decrease the substantial morbidity and mortality rates associated with current patterns of surgical care for patients with pancreatic cancer (13).

A survey of 2.5 million complex surgical procedures in the USA showed a strong inverse relationship between hospital volume and case mortality rates for pancreatic resection. Also, long-term survival after pancreatic cancer resection is superior in high-volume centers (14-16).

DIAGNOSIS OF RECURRENCE

CT is a valuable imaging method used to assess the surgically treated pancreatic cancer patient with or without adjuvant therapy (chemo- or/and radiation therapy). CT can detect postoperative complications, local recurrences or distant metastases. The site of recurrence after surgery is dependent on the site of the primary tumor in the pancreas and lymphatic drainage routes. But local changes following therapy are difficult to be differentiated from recurrent tumor tissue that is why very important is the first postoperative examination which will be used as a baseline for subsequent comparison of findings.

For metastatic disease the authors advocate imaging during the portal venous phase which can better detect liver metastases and the use of thin sections imaging to improve the detection of locally recurrent disease (2).

The possible role of PET in detecting recurrent local or metastatic disease is still a matter of study. It is rather useful in clarifying the CT examinations which are equivocal for recurrent disease. This was suggested by the results of a small study of 20 patients operated for pancreatic cancer using a Whipple procedure (17).

Many reports showed that FDG-PET (fluorine-18-2-fluoro-deoxy-D-glucose positron emission tomography) is useful for the early detection of recurrence in cancers of different organs. But actually there are only a few reporting its use for recurrent pancreatic cancer.

Tanizawa et al. have evaluated the use of FDG-PET for the diagnosis of recurrence of pancreatic cancer. When the recurrence could not be confirmed by computed tomography (CT) or magnetic resonance imaging (MRI), the final diagnosis can be made by FDG-PET. The use of FDG-PET also allowed for early detection of recurrent lesions after surgical resection for pancreatic cancer (18).

Abdominal ultrasound is a reliable method for monitoring the patients with pancreatic resections. It is non-invasive, cheap and it could be used as the first intention imaging technique.

In the management of pancreatic cancer, due to early cancer recurrence and death, the development of surgical techniques was focused on the prevention of early postoperative complications. But the long-term survival following pancreatoduodenectomy is increasing slightly in the last 2 decades and, consequently, the preservation of both endocrine and exocrine function of the remnant pancreas is becoming more important.

Experimental Wirsung duct ligation lead to destruction and progressive fibrosis is replacing the normal pancreatic tissue, although the islets are relatively well preserved for a period of time (19-21). Different degrees of fibrosis of the remnant pancreas following pancreaticoduoden-ectomy have been identified at autopsy, but the assessment of fibrosis in the pancreatic remnant is difficult during life.

Dynamic contrast-enhanced MRI is a reliable and non-invasive method for evaluating fibrotic changes in the remnant pancreas after pancreaticoduodenectomy. A duct-to-mucosa pancreatojejunal anastomosis was associated with a lower risk of residual pancreatic fibrosis than a pancreatojejunoserosal technique (22).

EUS-FNA has a reported sensitivity of 85% and specificity of 98% for the initial diagnosis of pancreatic cancer. Concerning the suspicion of pancreatic cancer recurrence EUS-FNA has a sensitivity ranging from 81% to 93%, which is similar to the sensitivity of 83% reported for fluorodeoxyglucose-positron emission tomography/contrast-enhanced CT.

The main advantage of EUS for this diagnosis is the ability to provide a tissue diagnosis in an otherwise often inaccessible region in which to perform percutaneous biopsy.

Being able to place a needle in these recurrent tumors, we surmise that EUS-FNA may also offer an opportunity to treat or aid in the treatment of these recurrences by fiducially placement, implantation of radioactive seeds, or fine-needle injection of ablative or chemotherapeutic agents (4).

Follow up marker. CA19-9 was first described by Koprowski et al. and is a tumor-associated carbohydrate antigen found on the cell surface of many gastrointestinal tumors. Koprowski immunized mice colorectal carcinoma cell lines and then isolated CA19 9 monoclonal antibody from mice splenocytes. Further research has shown that the antigen is normally present in salivary mucus and exocrine pancreatic juice, so, even if it was originated from colorectal carcinoma cell lines, it is very useful in the diagnosis, assessment and follow-up of the patients with pancreatic cancer (23-25).

Some investigators have tried to demonstrate the usefulness and effectiveness of sequential detection of CA19-9 serum levels in postoperative follow-up period.

Probably the earliest study was performed in 1986 at the National Cancer Institute and the authors found out that a

decrease to normal level after surgery was associated with longer survival compared with the patients whose CA19 9 level remained high. Also they demonstrated that the increase of CA19 9 level >95U/mL or a fourfold increase from the lowest postoperative level predict disease progression (26).

Montgomery et al. found that postoperative CA 19-9 level measurement is the best predictor of disease-free and also of overall survival. They found that patients whose CA 19-9 levels returned to normal by 3 to 6 months had a longer disease-free survival and overall survival than those with a steady level. The survival of patients with postoperative CA 19-9 level of less than 180 U/mL at 1 to 3 months was similar to that of patients whose levels normalized by 3 to 6 months (27).

They concluded that patients who present with undetectable preoperative CA19-9 levels and potentially resectable pancreatic cancer, regardless of advanced stage, should be considered candidates for aggressive therapy.

Adjusted baseline CA 19-9 may be a better clinical application for estimating survival or recurrence risk than serial values. Different treatment strategies can be individualized based on baseline preoperative levels. Chemo radiation or postoperative adjuvant therapy could be planned based on the risk of recurrence estimated by the preoperative adjusted CA 19-9 (28).

Treatment. In most cases re-intervention for local recurrence carry a bad prognosis because many patients have a R1 resection in secondary intervention. Repeat pancreatectomy might bring about a favorable effect on the prognosis in the patients with isolated local recurrence in the remnant pancreas if R0 resection is expected to obtain a repeat pancreatectomy.

Diagnosis of a distant metastasis is an important criterion in selecting candidates for repeat pancreatectomy. During the follow-up after initial pancreatectomy the serum level of tumor marker (CA19-9) should be determined and CT, MRI and PET scans for differentiating the three different patterns of local recurrence (lymph nodes, soft tissue, and remnant pancreas) should be performed.

Repeat pancreatectomy in these patients might bring about favorable effects on the prognosis without an increase in operative morbidity and mortality; the patient should be carefully assessed in order to determine whether he/she might be a good candidate for repeat pancreatectomy (29).

Sunogozaka et al. reported the case of a patient diagnosed with recurrent pancreatic cancer and treated with UFT (uracil-tegafur) combined gemcitabine (GEM) combined chemotherapy. After one cycle of therapy, the anti-tumor effect was progressive disease with obstructive jaundice and enlargement of lymph node metastasis and liver metastasis. Chemotherapy was changed to TS-1 (tegafur + gimestat + otastat potassium) combined GEM chemotherapy and resulted in partial response. The only adverse effect was a grade 3 leukopenia.

The authors support the idea that some cases may be effectively treated by TS-1 combined chemotherapy after treatment failure of UFT combined GEM chemotherapy. The therapy is simple and possible to continue safely on an ambulatory basis while maintaining quality of life (30).

Chemoradiotherapy for local recurrence. In patients with no further surgical option in local relapse, the palliative treatment (chemoradiotherapy) is preferred, radiotherapy having the greatest impact on

locoregional disease control, and is affected by hypoxia-related tumor radioresistance (i.e. pancreatic cancer seems to be extremely hypoxic according to several studies). Several trials using simultaneous chemoradiotherapy (CRT) with gemcitabine, 5-FU or cisplatin have shown that high efficacy can be achieved locally. Based on trials, combined CRT is suggested to be superior to chemotherapy or radiotherapy alone in patients presenting with de novo locally advanced pancreatic cancer.

Stereotactic body radiation therapy-cyberknife. Radiotherapy in the patient with unresectable locally advanced disease shows unsatisfactory local control because therapeutic radiation dose to the pancreatic tumor is limited by the sensitivities of surrounding tissues. The cyberknife system is being used since 2001 to deliver radiation to any human radiosensitive tumor; cyberknife offers a stereotactic boost of radiation therapy alone or in combination with conventional radiation therapy.

There are few studies that demonstrate that cyberknife therapy for unresectable pancreatic carcinoma can be delivered in three fractions with minimal morbidity and a local tumor control rate of 91.7%.

In unresectable pancreatic cancer the most commonly used treatment options are chemotherapy with 5-fluorouracil and/or gemcitabine, palliative surgical bypass procedures, palliative radiation procedures or other palliative measures. For recurrent pancreatic cancer, there are no established therapeutic strategies although the pathophysiological pattern of recurrence is well known (31).

CONCLUSIONS

Recurrence of pancreatic cancer is attributed to either occult systemic disease at the time of diagnosis or the presence of macroscopically (R2) or microscopically (R1) positive surgical resection margins. It usually occurs within 2 years after surgery as migratory metastases along major upper abdominal arteries and veins to the liver or peritoneum (70%) and less commonly as loco regional disease as masses closely applied to the surgical margins in the neck or body of the pancreas (30%).

The treatment of local recurrence may include surgical resection alone or combined chemo radiotherapy.

The vast majority of patients develop recurrence within 2 years postoperatively, suggesting the necessity of a consensus on the optimal and more intensive follow-up during the first 2 years after surgery.

SHEAR BOND STRENGTH OF CALCIUM ENRICHED MIXTURE CEMENT AND MINERAL TRIOXIDE AGGREGATE TO COMPOSITE RESIN WITH TWO DIFFERENT ADHESIVE SYSTEMS

The aim of a study realized by a group of iranian researchers was to evaluate the shear bond strength of recently used pulp capping materials: white mineral trioxide aggregate, and calcium enriched mixture cement to composite resin with the use of etch-and-rinse and self-etch adhesive systems and compare them with the bond strength of commonly used resin modified glass ionomer cement. Forty specimens from each test material were fabricated, measuring 4 mm in diameter and 2 mm in depth. The specimens of each material were divided into 2 groups of 20 specimens according to the adhesive system (Single Bond vs. Clearfil SE Bond) used for bonding of resin composite. The shear bond strength values were measured at a crosshead speed of 1.0 mm/min and fractured surfaces were examined. Data were analyzed using two-way ANOVA and a post hoc Tukey's test ($P<0.05$). The analysis of data showed a significantly higher bond strength for resin modified glass ionomer cement compared to white mineral trioxide aggregate and calcium enriched mixture cement ($P<0.001$); however, no significant differences were observed in the bond strength values of white mineral trioxide aggregate and calcium enriched mixture cement ($P=0.9$). Furthermore, there were no significant differences in relation to the type of the adhesive system irrespective of the type of the material used ($P=0.95$) All the failures were of cohesive type in resin modified glass ionomer cement, white mineral trioxide aggregate and calcium enriched mixture cement. In conclusion, bond strength of resin modified glass ionomer cement to composite resin was higher than that of white mineral trioxide aggregate or calcium enriched mixture cement irrespective of the type of the adhesive system (Savadi Oskoee S, Bahari M, Kimyai S, Motahhari P, Eghbal MJ, Asgary S. Shear bond strength of calcium enriched mixture cement and mineral trioxide aggregate to composite resin with two different adhesive systems. *J Dent (Tehran)*, 2014; 11 (6): 665-671).

ST SEGMENT DEPRESSION IN ASYMPTOMATIC MALE PATIENT WITH NORMAL CORONARY ARTERIES (Abstract): ST segment depression and T waves inversion are electrocardiographic (ECG) repolarization abnormalities often encountered in clinical medical practice that have been proved to predict future cardiovascular events. We present the case of a 62-year-old male patient, asymptomatic, with ST segment depression and inverted T waves discovered incidentally on resting ECG. Echocardiographic and laboratory examinations ruled out multiple causes of ECG abnormalities. Suspecting a silent myocardial ischemia, an ECG exercise stress test was performed; it revealed pseudo normalization of T waves during exercise and early recovery phase. Being inconclusive, a coronary CT was the final election test; it showed normal coronary arteries with no stenosis, the patient being scheduled for regular follow-up. The possible causes of ST segment depression are reviewed since it is important that early cardiovascular signs especially in asymptomatic patients to be prevented and detected. **Keywords**: ST SEGMENT DEPRESSION, INVERTED T WAVE, ASYMPTOMATIC, NORMAL CORONARY ARTERIES.

ST segment depression and T wave inversion have been identified as markers of future cardiovascular events in patients with or without coronary artery disease (CAD). Most of the ST segment and T wave changes are represented by primary repolarization abnormalities while secondary changes belong to abnormalities of depolarization (1). Theoretically, ST segment displacement should be measured at 40 or 80 ms after the J point in three consecutive beats with a non-modified baseline (2). Our aim is to present a comprehensive evaluation of different causes of ST segment depression in an asymptomatic male patient.

CASE REPORT

We present the case of a 62-year-old male patient, occasional smoker, totally asymptomatic, who was admitted to our department for evaluation of electrocardiographic (ECG) changes discovered incidentally three months earlier when the patient underwent surgery for a lumbar herniated disc.

Patient's case history was short: surgery treatment for herniated disc L4-L5, L5-S1 and recent diagnosis of benign prostatic hyperplasia. The highest known systolic blood pressure (BP) was 140 mm Hg with no other cardiovascular diseases. The patient did not follow any chronic medical

treatment.

Clinical evaluation revealed an overweight patient (body mass index 27 kg/m²), with normal pulmonary and cardiovascular examination findings, resting BP 120/80 mmHg and heart rate (HR) 70 bpm.

Laboratory results showed normal full blood count with no inflammatory syndrome, normal glucose, hepatic and renal parameters. The patient presented borderline values of total cholesterol and LDL-cholesterol (209 mg/dl and 124 mg/dl, respectively) while HDL-cholesterol and triglycerides levels were normal. Potassium and uric acid levels were unaltered.

ECG at rest revealed sinus rhythm, 70 bpm, intermediate axis, ST segment depression (maximum 2 mm) with inverted T waves in precordial leads V3-V6 (fig. 1). Even though R waves in V5 and V6 leads were of moderate amplitude, the patient did not meet any criteria for a diagnosis of left ventricular hypertrophy (LVH) (3).

Taking into consideration the ECG modifications, we performed a 2D Doppler trans thoracic echocardiography that revealed normal left ventricular wall sizes with normal kinetic movement and preserved LV ejection fraction. Thus, the diagnosis of LVH (LV mass index = 96 g/m²) and obstructive hypertrophic cardiomyopathy were ruled out as possible causes of ST segment depression.

As the patient approved to participate in a study assessing subclinical atherosclerosis in patients with no prior diagnosis of cardiovascular or metabolic diseases, we performed the carotid ultrasound and found a moderately increased intima-media thickness (1 mm) with a small calcified plaque on the right carotid bulb. Arterial stiffness was also within the normal range, (aortic pulse wave velocity - 6.9 m/s). Ankle-brachial index was within the normal range.

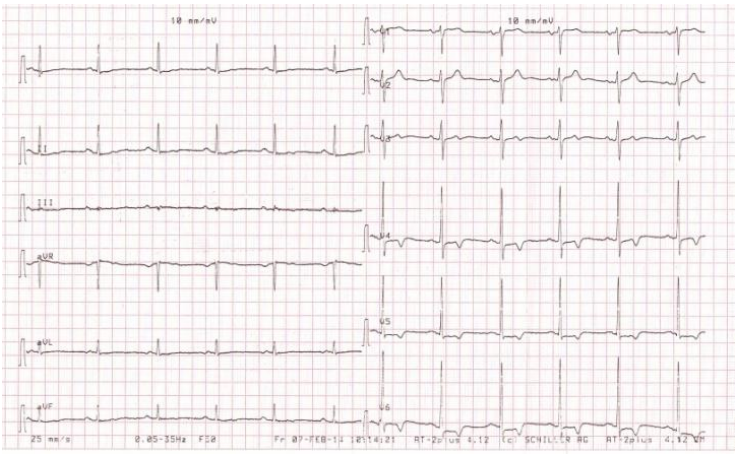

Fig. 1. ECG at rest: sinus rhythm, 70 bpm, ST segment depression and inverted T waves in leads V3-V6

At that moment, we suspected a silent myocardial ischemia. Analyzing the latest guidelines for stable coronary artery disease, the patient presented a 44% intermediate pre-test probability of CAD (4). For intermediate pre-test probability, exercise ECG is the most feasible initial diagnostic test. Thus, an exercise stress testing on

cycloergometer was performed: the patient reached maximum HR (161 bpm, 101% of age-predicted HR), with a work-load of 125 W and 6.5 METs. The patient did not complain of any chest pain or other clinical symptoms. Compared to the resting ECG, T waves were positive in leads V4-V6 and remained positive 6-7 minutes during the recovery phase (fig. 2, 3).

Exercise ECG being inconclusive for making a diagnosis of CAD, we resorted to a more accurate method, the coronary computed tomography angiography (coronary CT) for several reasons. It has a sensitivity of almost 95-99%, being the test with the highest negative predictive value; it is considered an alternative to other stress tests for ruling out CAD in intermediate pre-test probability patients; it is considered in intermediate pre-test probability patients after an inconclusive exercise ECG (4). Our patient meeting all the above mentioned criteria, a coronary CT was performed; it revealed permeable coronary arteries with no stenosis and with Agatston calcium score equal to 0.

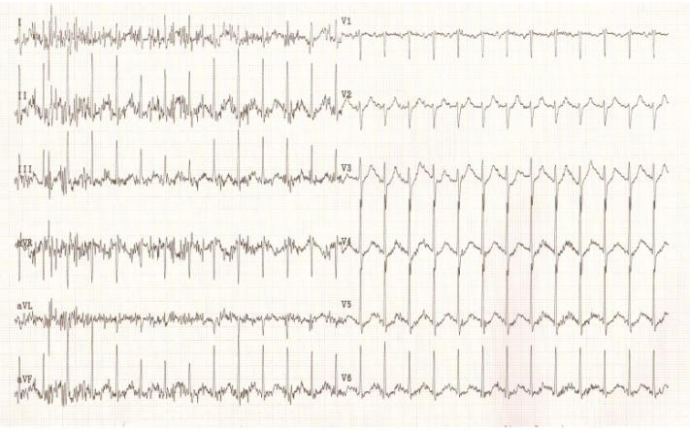

Fig. 2. Exercise ECG – at maximum HR: pseudo normalization of T waves

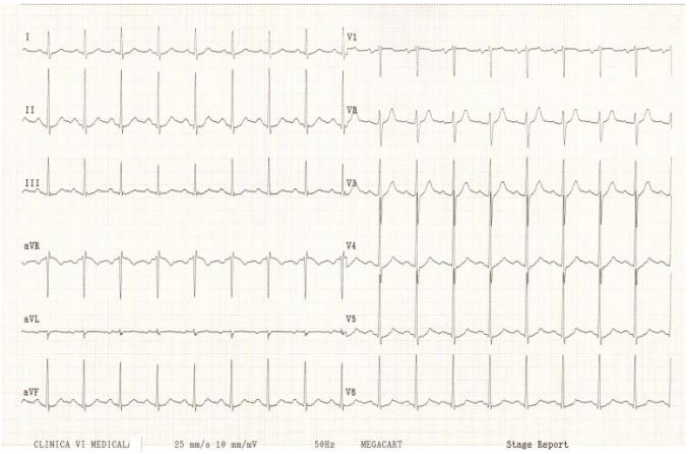

Fig. 3. Recovery phase (5'): still positive T waves with mild ST segment depression

Thus, we excluded all possible causes of ECG ST segment depression. The patient is currently under no chronic treatment and is scheduled for regular follow-up visits in our clinic.

DISCUSSION

ST segment depression and negative T waves are common electrocardiographic changes often seen in medical practice. They need an accurate approach in order to differentiate the possible causes both in acute and in chronic situations.

We will make a summary and comprehensive review of the multiple causes of ST segment depression and T wave inversion based on the above presented clinical case.

When encountering such resting ECG incidentally and not in acute situation, the first diagnostic hypotheses are represented by LVH and myocardial ischemia. Our patient did not meet any of the *left ventricular hypertrophy* ECG criteria (3). However, we performed an echocardiography taking into consideration the poor correlation between ECG and echocardiographic diagnosis of LVH and the result was negative as well. The normotensive status of the patient was another argument in favor of the absence of LVH. On the ECG, the patient did not present *left bundle branch block* and the cardiac ultrasound ruled out the *obstructive hypertrophic cardiomyopathy* as other possible causes of ECG abnormalities.

Another possible cause of ST segment depression could be *Wellens syndrome* which is characterized by two patterns. 75% of cases consist in symmetrically and deeply inversed T waves in leads V2-V4. In 25% of cases, T waves have positive-negative biphasic morphology in leads V2-V4 and the patient usually presents a 90% proximal left anterior descending stenosis (1). However, our patient has no coronary lesions and his ECG findings were different.

There were no *acute causes* that could lead to ST segment depression such as myocardial infarction or pulmonary embolism and by using laboratory results we excluded *hypokalemia*. The patient's medical history ruled out the *digitalis toxicity* as other possible cause.

After interpreting all the results, our main concern was represented by *silent myocardial ischemia*. Asymptomatic myocardial ischemia is present in up to 24% of apparently healthy individuals while in diabetic population the prevalence varies between 12% and 33%. In subjects without prior diagnosis of coronary disease, ST segment depression can predict adverse cardiovascular events and its detection by ambulatory electrocardiogram is a more powerful predictor of mortality than age, exercise duration, hypertension or diabetes (5).

As our patient had an intermediate pretest probability of having CAD, we performed an exercise ECG stress test that showed pseudo normalization of T waves during exercise and within the first minutes of the recovery phase. Nowadays, transient conversion of T waves is considered a nonspecific finding in individuals without prior myocardial infarction and the diagnosis of certainty should be made by using other tests (2).

Finally, the patient having a normal CT coronary angiogram, there were two major hypotheses to explain the ECG abnormalities: an incipient LVH or an atypical *micro vascular angina*.

Coronary micro vascular dysfunction is usually associated with advanced age, hypertension, dyslipidemia and diabetes, but

also with chronic inflammation (high levels of C-reactive protein). Our patient had some of these risk factors, but at lower levels (62 years, arterial hypertension grade I, mild hypercholesterolemia). On the other hand, this specific type of angina is more prevalent in women than in men. However, our patient presented no clinical symptoms at rest or during stress-induced angina. Currently, the gold standard for a certain diagnosis is represented by invasive coronary vasomotor testing using intracoronary injection of acetylcholine (6).

Even if the patient did not meet electrocardiographic or echocardiographic criteria for LVH, this possible diagnosis should be maintained and a regular follow-up should be scheduled. It has been proved that LVH is associated with markers of subclinical atherosclerosis e.g. carotid-intima thickness and carotid plaques as it is the case in our patient (7, 8). However, arterial stiffness was not pronounced and the ankle-brachial index was normal.

It is worth mentioning the research of Kansal et al. who performed a study in which they correlated the presence of resting ST segment depression with coronary angiography in 37 patients free of recent coronary events and with no other cause of ST segment abnormality. Of 37 subjects, 9 had normal coronary angiograms, but 8 of them were females and had a relatively low mean age (43.8 years). The same study reported a double risk for occlusive CAD in men compared to women (9). Another study conducted only on male population pointed out those patients with resting ST segment depression and no prior myocardial infarction had a higher prevalence of severe CAD. After a 4.4-year follow-up, individuals with ST segment depression at rest (with or without prior myocardial infarction) had lower rates of survival compared to general population (10).

CONCLUSIONS

This case report presents a comprehensive management of an asymptomatic male patient, with a moderate cardiovascular risk, that presents with a resting ECG pattern of ST segment depression and inverted T waves in leads V3-V6. By multiple echographic, laboratory and stress tests we ruled out the possible causes of the ECG abnormalities. Using coronary CT, the end result (normal coronary arteries) was surprising so that the exact cause could not be determined and a certain diagnosis made. Thus, it is very important to closely follow-up such patients in order to prevent and promptly diagnose future cardiovascular changes and events.

ANTIOXIDANT ACTIVITY OF PHENOLICS IN RED WINE

It is known that health benefits of red wine have been linked to the presence of phenolic antioxidants. Thus, a group of researchers developed a high performance thin layer chromatographic (HPTLC) method combined with high resolution digital plate images. They visually compared multiple wine samples simultaneously on a single chromatographic plate and quantified levels of four representative classes of phenolics found in wines: gallic acid, caffeic acid, resveratrol and rutin. They also investigated the contribution of these phenolic compounds to the total polyphenolic content (TPC) and total antioxidant capacity (TAC) of the wine samples. The average concentrations of caffeic acid, gallic acid, resveratrol, and rutin in the red wines were 2.15, 30.17, 0.59 and 2.47 mg/L respectively with their concentration below limit of quantification in the white wine samples. The highest concentration of resveratrol and rutin is found in the Cabernet and Shiraz wine samples. The amounts of gallic acid are correlated with TPC ($r = 0.58$). Italian wines have the highest correlation between TPC and TAC ($r = 0.99$) although they do not contain detectable amounts of resveratrol, they contain significant amount of rutin. Researchers concluded that antioxidant properties might be associated with the presence of flavanols in wines. The antioxidant activity of phenols is also related to their chemical structure, especially with the number and arrangement of free hydroxyl groups of polyphenol skeleton (Agatonovic-Kustrin S, Hettiarachchi CG, Morton DW et al. Analysis of phenolics in wine by high performance thin-layer chromatography with gradient elution and high resolution plate imaging. *J Pharmaceut Biomed* 2015; 102: 93–99).

MANAGEMENT OF RENAL COLIC DURING PREGNANCY (Abstract**):** The diagnosis of urological diseases in pregnancy involves particularities requiring both the knowledge of the pathophysiological mechanisms of the respective diseases and a experience of the urologist and gynecologist in assessing the physiological conditions of pregnancy. **Aim**: To identify the specific features of renal colic in pregnant women, in the context in which the urological assessment of them is not mandatory. **Material and methods:** The study included a group of 86 pregnant women diagnosed with urological diseases and renal colic as their main symptom. **Results**: There are two major difficulties faced by urologists in these cases: firstly, the impossibility of conducting X-ray imaging investigations to determine the location and type of the obstruction and, on secondly, the ureteral catheterization and insertion of the ureteral catheter in the absence of adequate fluoroscopic control. **Conclusions**: The urologist's experience is decisive in establishing intraoperatively if the introduction of the ureteric probe is possible, the risk of a ureteral perforation with severe consequences requiring a percutaneous nephrostomy to be performed under ultrasound guidance. **Keywords:** PREGNANCY, RENAL COLIC, URINARY DISEASES.

During normal pregnancy there are profound changes in the genitourinary tract affecting the pregnant woman. Management of urological emergencies during pregnancy remains a challenge because clinical signs are subtle diagnostic tools and treatment options are limited.

Mild symptoms of urinary tract infection, urolithiasis or hematuria can progress to true medical emergencies with devastating results for the mother and the fetus if they are not diagnosed and treated promptly (1).

The clinical picture of urological conditions during pregnancy is like the manifestations of these diseases in other categories of patients, but differences may occur in their progression and complications through effects for both mother and fetus.

Urological disorders that may occur during pregnancy are acute hydronephrosis of pregnancy, infections, urinary lithiasis, kidney failure, and clinically these manifestations are dominated by pain, septic status or symptoms associated with impaired renal function.

The aim of this study was to evaluate the issue of the diagnosis of certainty and

the optimal therapeutic choice, related to a symptom that affects relatively frequently (11-20%) pregnant patients - renal colic. Because the number of patients presenting to urology clinics is increasing, it is necessary to standardize the methods for diagnosis and treatment of these diseases, with the implementation of a patient management protocol.

MATERIAL AND METHODS

This retrospective study was performed in a group of 86 patients of different gestational age that experienced this symptom. The reasons for the presentation, age of the patients, gestational age, and the differential diagnosis were considered.

In this research, the STATISTICA program, dedicated to medical research, was used for statistical data processing. The following tests were used: ANOVA, Scheffé, Pearson, Mantel-Haenszel, Fisher test, and specific correlation tests for quantitative and for qualitative variables.

Following these tests, the main parameters of interest were discussed and, according to their values, the conclusions were drawn.

RESULTS

The analysis of the age of patients with urological disorders during pregnancy revealed a high frequency of cases between the age of 25 and 30 years (35.76%). Comparable frequencies were recorded for the age groups 15-20 years - 15.15%, 30-35 years - 16.97%, and 20-25 years - 25.45%. A lower incidence of urological disease in pregnancy was found in patients over 35 years of age.

There was a high frequency of cases in the second and third trimester of pregnancy, with a very low number of pregnant women in the first trimester of pregnancy - 9.09% (fig.1).

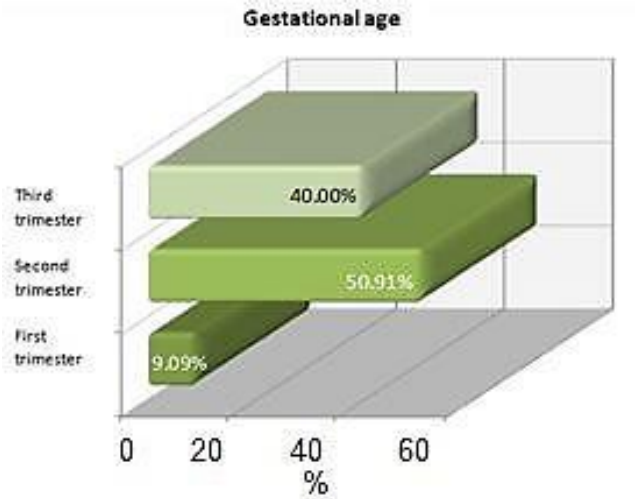

Fig. 1. Distribution of cases by age of pregnancy

The number of pregnancies has a homogeneous distribution, the highest frequency being found for cases with 1 or 2 pregnancies, representing 69.09%. Pregnant women at the 3-rd pregnancy accounted for 30.91% of the study group (tab. I).

TABLE I

Statistical indicators of the number of pregnancies in the study group

Average value of the number of pregnancies	Average -95%	Average +95%	Std. Dev.	Std. Er	Min	Max	Q25	Median	Q75
2.15	1.97	2.33	1.18	0.09	1	6	1	2	3

The main reason for admission was the presence of collateral lumbar pain, which was identified in 82 cases. Absence of lumbar pain was very rare, in just 4 cases.

The diagnosis on admission was ureterohydronephrosis in 52.12% of cases, infected ureterohydronephrosis in 26.67%, and acute pyelonephritis in 15.15% of pregnant women.

A diagnosis of lumbar ureteral calculi was made in 3.3% of cases and of pelvic ureteral calculi in 3.03% (fig. 2).

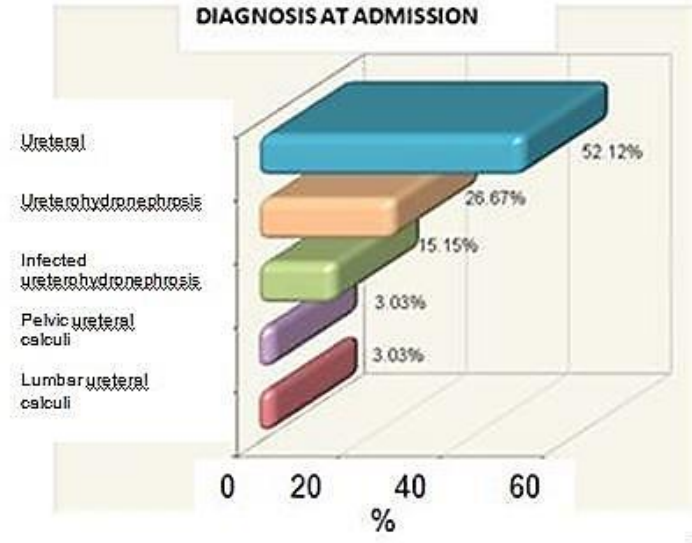

Fig. 2. Distribution of cases based on patient diagnosis

The urological history of pregnant women in the studied group was most frequently represented by the spontaneous elimination of calculi (8.48%) and histological documented lithiasis episode (2.42%).

In our study most, pregnant women did not have a history of urinary disease (89.09%), which shows that pregnancy makes it that the pathological urological aspects that were clinically silent before pregnancy to become clinically manifest.

In this study, the results of the multiple correlations were considered considering

the changes in the admission profile of pregnant women with urological disorders. The insignificant value of the significance level (p) calculated for the intercept variable indicates that besides the factors under study there are no other predictive factors in determining the pursued profile (tab. II, fig. 3).

TABLE II

Multiple correlation of pregnancy age *vs.* clinical aspects on admission

Partial correlation	Coefficient of correlation (Beta)	Std. Err. (Beta)	B	Std. Err. B	t	p *95% interval of confidentiality*

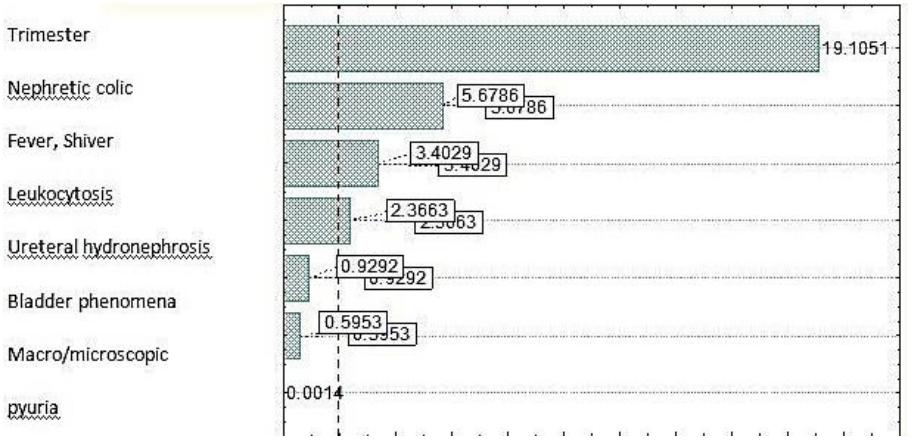

Fig. 3. Statistical t-values in the multiple correlation of the age of pregnancy *vs.* clinical findings on admission

Lumbar pain was located on the right side in 43.64% of pregnant women in this study, while in 18.79% it was bilateral. Left-side location was reported in 35.15%

of cases (fig. 4).

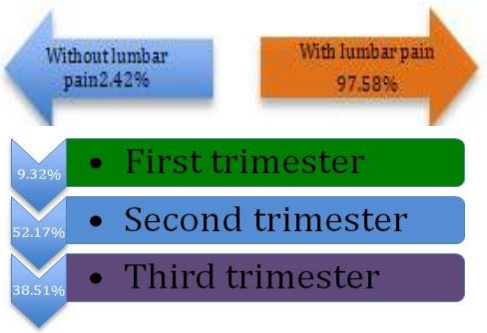

Fig. 4. Clinical aspects on admission - lumbar pain *vs.* trimester of pregnancy

DISCUSSION

Renal colic on admission was particularly noted in patients in the second trimester of pregnancy (52.17%), the results demonstrating a significant correlation between the age of pregnancy and the incidence of lumbar pain ($\chi^2 = 6.14$, $p = 0.036$, 95% CI). The results of the study are consistent with literature data (2).

The statistical data show that the incidence of urological diseases during pregnancy is significantly higher in primiparas women (35.15%) than in the other pregnant categories studied.

The clinical findings on admission have shown a significant correlation with the age of pregnancy, a conclusion demonstrated by the results of the multiple correlation test (3).

In other words, the age of pregnancy significantly influences the clinical aspect of pregnancy-related urological conditions. To highlight the most relevant clinical and laboratory findings depending on gestation age, multivariate analysis was used.

The results of multivariate analysis indicate the predictive factors of the profile of pregnant women with urological disorder and gestational age.

Correlation analysis using nonparametric tests demonstrated the association between the presence of lumbar pain and the trimester of pregnancy by the high value of the non-parametric correlation coefficient and low significance level of the test. In statistical estimations a 95% confidence interval was used.

Ureteral calculi during pregnancy represent not only a diagnostic challenge, but also a management dilemma. Some studies report an incidence of symptomatic urolithiasis during pregnancy of 0.35%, occurring especially in the third trimester of pregnancy (55.5%) (4).

The reported incidence of symptomatic nephrolithiasis during pregnancy varies greatly between 1 in 244 pregnancies to 1 in 1,240 pregnancies (5). The occurrence of urolithiasis during pregnancy is a risk not only for the mother but also for the fetus and may be a factor which contributes to premature birth. The diagnosis during pregnancy is difficult, primarily because of limitations of X-ray use and physiological hydronephrosis during pregnancy (6). In cases requiring invasive treatment, double-J stent or percutaneous nephrostomy may be used, which are the less invasive techniques for urinary drainage. The insertion of a double-J catheter can be performed under control until the end of pregnancy. Percutaneous nephrostomy can also be performed with local anesthesia under ultrasound guidance, realizing an external drainage without irritation of the bladder.

In rare situations where obstruction is bilateral, the colic is accompanied by oliguria or even anuria. These urinary phenomena may be accompanied by reflexive digestive manifestations, namely nausea, vomit-

ing, or ileus which may sometimes be severe. These symptoms may be explained by the direct compression in pregnancy on the celiac plexus and the phenomena of angiogenesis and vascular hypertrophy.

Renal colic is the most common manifestation of acute hydronephrosis in pregnancy and occurs in most cases on the right side. In contrast to colic of lithiasis where there is typically no antalgic position for the patient, in the colic of hydronephrosis the pain improves or even disappears if the pregnant woman is lying on the opposite side to the painful one (7).

During pregnancy, symptomatic urolithiasis associated with ureteral obstruction and upper urinary tract infection is a major urological emergency that may cause perineal urosepsis, or even patient death. Also, the presence of urinary calculi can cause premature rupture of membranes and premature birth in a percentage ranging from 2.9% to 7%, presenting a high degree of risk for the fetus.

The presence of an associated pathology in pregnant women, e.g. hypothyroidism, further complicates the situation and outcomes of treatment, raising doubts about the continuation of pregnancy (8).

These reasons lead to the conclusion that although urolithiasis is a relatively rare condition during pregnancy, its correct approach requires a very good collaboration between obstetricians, urologists, radiologists and anesthetists.

Renal colic during pregnancy can be determined by both acute gestational hydronephrosis and intrinsic obstruction caused by a calculus in the excretory pathway. Differential diagnosis can only be made when the ultrasound directly shows the presence of calculi in the pyelo-ureteral junction or in the first portion of the lumbar ureter. Whatever the cause, renal colic pain should be treated as a matter of urgency. Minimal or non-invasive imaging techniques are preferred. The inflammation of the fascia overlying the neighboring organs can be distinguished by MRI. Anatomical imaging evidence is extremely valuable in differential diagnosis (9,10).

Urological complications in pregnancy are caused by pain and can take the form of uterine contractions and fetal distress. If urine is infected, there may be bacteremia, septicemia, or even toxic-septic shock that may result in fetal and even maternal death. A rare, but very severe complication is the spontaneous rupture of the kidney that is often fatal (11, 12, 13, 14).

CONCLUSIONS

In our study the clinical picture of the patients is almost like the manifestations of other urological diseases; differences that can occur in the disease course and complications could affect both the mother and the fetus. Our statistical data show that the incidence of urological diseases during pregnancy is significantly higher in primiparas women. The imaging investigations should be performed due to the possible harmful effects on the product of conception. In the studied group we were able to make an ultrasound diagnosis so that it was not necessary to use X-rays in any case. The renal colic will be initially treated conservatively by controlled ingestion of fluids, antalgic and antispasmodic drugs, and in the case of hyperalgesicor febrile colic the emergency drainage of the upper urinary tract, most commonly performed by ureteral catheterization or percutaneous nephrostomy.

A NEW APPROACH TO SKIN CANCER DIAGNOSIS: THE ELECTRICAL IMPEDANCE SPECTROSCOPY

In a study by L. Rocha et al. the effect of adding electrical impedance spectroscopy (EIS) measurement at baseline to suspicious melanocytic lesions undergoing routine short-term sequential digital dermoscopy imaging (SDDI) was assessed. Patients with suspicious melanocytic lesions eligible for short-term SDDI were evaluated with EIS measurement which was performed at the first visit following SDDI. Melanocytic lesions with an EIS score ≥ 7 were excised because of the high risk of melanoma while lesions with a score < 7 were monitored with standard SDDI over a 3-month period. The results showed that an EIS score ≤ 3 requires no SDDI and values ≥ 7 require immediate excision of melanocytic lesions reducing the need for SDDI. The study offered a new approach to skin cancer diagnosis and showed that new protocol combining EIS at baseline with SDDI reduced the need to proceed to SDDI in just under half of cases. (Rocha L., Menzies S.W., Lo S. et al. Analysis of an electrical impedance spectroscopy system in short-term digital dermoscopy of melanocytic lesions. *BJD* 2017 Oct. 11. doi:10.1111/bjd.15595).

CHRONIC VENOUS DISEASE CASES AT THE IASI DERMATOLOGY CLINIC (Abstract): Chronic venous disease (CVD) is defined as a disturbance of blood return to the deep venous system, superficial venous system, and communicating (perforating) veins. Once present, CVD persists throughout life, so like heart failure it is nowadays considered "a condition for life". Severe CVD of the lower limbs is one of the most common medical problems, affecting up to 25% of the general adult population of industrialized countries. **Aim**: to determine the incidence of CVD among the cases admitted to the Dermatology Clinic of the "Sf. Spiridon" Emergency Clinical Hospital Iasi, CVD incidence by sex, age, area of residence and the main pathogens incriminated in super infection of ulcerative lesions. **Material and methods:** We did a retrospective study of patients admitted to the Dermatology Clinic of the Iasi "Sf. Spiridon" Emergency Hospital over a five years period. **Results:** Of the total number of patients admitted to our clinic (9375), 57% were diagnosed with CVD and 26.61% of them were with CEAP 6 class chronic venous insufficiency. There was an approximately equal sex distribution and most patients (44%) were older than 65 years. **Conclusions: W**e did a large epidemiological study of venous disease, based on revised CEAP classification, showing again that it is not only a very important medical problem, with various clinical manifestation and multidisciplinary approach, but also an important issue for health insurance system. **Keywords:** CHRONIC VENOUS DISEASE, EPIDEMIOLOGY, COMPLICATIONS.

Chronic venous insufficiency (CVI) is not a medical problem exclusive for dermatology, general practitioners, phlebologists, internists also treat patients with this disease. Severe chronic venous disease (CVD) of the lower extremities is one of the most widespread diseases, affecting up to 25% of the general adult population of developing and developed countries (1).

CVI is a common health problem, characterized by symptoms and signs occurring as a result of structural and functional alterations of the veins. Characteristic **symptoms** are heavy, tired, swollen legs, predominantly nocturnal leg cramps, pain and burning sensation in the leg, and itching. **Signs** include telangiectasias, reticular veins, varicose veins, edema, and such trophic skin changes as lipodermato-sclerosis, dermatitis, pigmentation, and, in end stages, ulceration (2, 3, 4). On the basis of this clinical symptoms and signs is made the clinical part of the CEAP classification of venous chronic insufficiency. According to CEAP classifi-

cation venous insufficiency is categorized depending on the severity of signs into 7 classes, C0 to C6, starting with C0 - no visible or palpable sign of venous insufficiency, C1 – telangiectasies or reticular veins, C2 – varicose veins; distinguished from reticular veins by diameter of 3 mm or more, C3 – edema, C4 – changes in skin and subcutaneous tissue secondary to CVD, now divided into 2 subclasses to better define the differing severity of venous disease: C4a – pigmentation or eczema, C4b – lipodermatosclerosis or atrophie blanche, C5 – healed venous ulcer and ending with C6 - varices associated with edema, trophic changes, open chronic leg ulcers. Each of this classes can be subdivided in S – symptomatic or A – asymptomatic. First used in 1994, and revised in 2004, CEAP basis classification is the most important clinical instrument for evaluation of patients with venous chronic disorder, and permits to separate patients with venous disease (C0-C2) from patients with venous insufficiency (C3-C6).

Worldwide, 10-33% of adult women and 10-20% of men have CVI. In the European countries the prevalence is even higher, 20 to 50%. In Romania recent epidemiological studies have shown a prevalence of CVI of 32% (5, 6, 7) in general population.

Factors that hinder venous circulation include: ankylosing arthrites of the knee and leg, plaster casts for lower limb fractures, leg bone malformations, accidental sectioning of lower limb motor nerves, neurological diseases with various motor deficits, oral contraception, etc (8, 9,10). Other important predisposing factors are represented by the association of CVD with cardiovascular diseases, caused and aggravated by alcohol and tobacco use, along with diabetes, obesity and occupations requiring prolonged standing such as: barber, cook, dentist, waiter, housekeeper, and last but not least sedentary life by lack of exercise, walking, outdoor physical activities (8,9,11). Aggravating factors are local infection, local allergy, and autoimmune factors (autoantibodies: against connective tissue, against vessel).

Pathophysiologically, the main deficiency leading to ulcerations and accounting for the difficulties encountered in their healing is the inability to adequately oxygenate tissues. It is an anoxia in a leg with adequate arterial flow. In addition, there is capillary thrombosis developed as a result of stasis, with permanent capillary loss. When the process is slow local fibrosis and sudden necrotic ulceration do occur. Sometimes, on the background of impaired oxygenation, infections or allergic processes develop, which can lead to ulceration if are not treated on time (2, 8, 10, 11, 12).

MATERIAL AND METHODS

This is a retrospective study of 5380 patients admitted to the Dermatology Clinic of the Iasi "Sf. Spiridon" University Emergency Clinical Hospital over a period of five years (January 1, 2009 – December 31, 2013) who met the diagnostic criteria for chronic venous disease. The aim of this study was to determine the incidence of CVD among the cases admitted to the Dermatology Clinic Iasi, the percentage of patients seeking medical attention by CVD stage, CVD incidence by sex, age, and area of residence, predisposing factors, and the proportion of patients in the various CVD classes according to revised CEAP basic classification.

In the patients diagnosed with CEAP class 6 CVI the discharge from ulcer surface was tested bacteriological to determine the degree of colonization of ulcerative lesions by pathogenic microorganisms and their sensitivity/resistance to antibiotics.

RESULTS

Of the 9,375 total number of patients admitted to our clinic over the study interval, 57.38% (5,380 patients) were diagnosed with CVD (fig. 1).

The percentage of patients hospitalized for CVD is significantly higher than patients hospitalized for other pathology - t calculated is 20.5 higher than t tabulated for p 0.001. Relative risk (RR) calculated for patients in the study is 1.2219 (95% CI: 1.1969 to 1.2474), with a z statistic of 19.04.

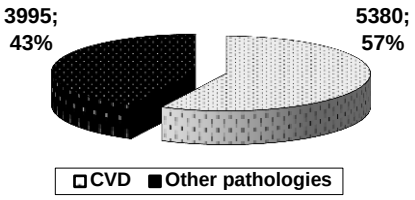

Fig.1. Ratio total admitted patients/CVD patients

From all the patients included in the study, CVD CEAP class 3 was the most common (2,089 patients, 38.83%), followed by CVI classes 6 with 1432 patients (26,61%) CVI class 4 with 1132 cases (21.04%), respectively.

A surprising thing is that throughout the study only 13 patients with CVD class 1 were diagnosed, suggesting that this common disease, with severe consequences, is under diagnosed in the early stages, when preventive measures, hygiene/dietary measures have maximum effect on disease course (fig. 2).

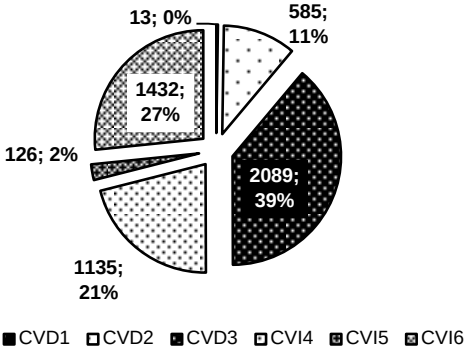

Fig. 2. Distribution of all patients by CEAP stage

The distribution of the patient by CEAP classes is almost the same in the years that we study, the number of cases being around the medium value of all cases introduced in our study (fig. 3).

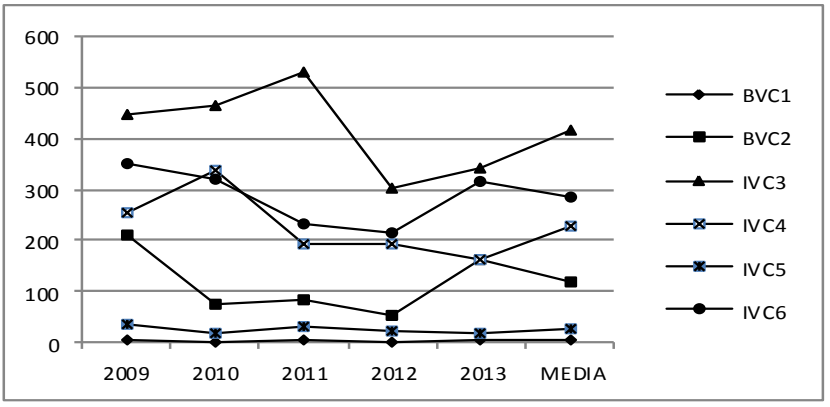

Fig. 3. Distribution of patients by CEAP stage and year

In absolute numbers, of a total of 9,375 patients hospitalized during the study interval, 5,380 had CVD in different stages, of which 1432 CVI CEAP class 6, accounting for 15.37% of all admitted patients in the Dermatology Clinic in the studied period (fig. 4).

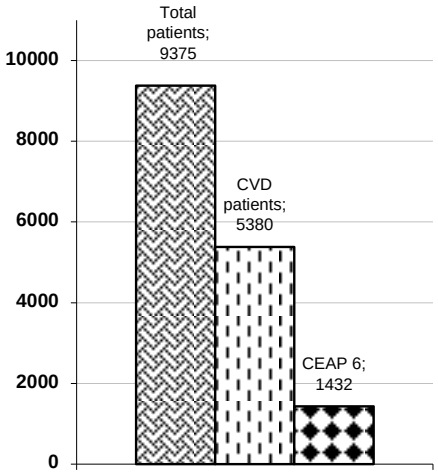

Fig. 4. Ratio total patients/CVD patients/ CVI 6 patients

According to new CEAP classification, from the total number of 5380 patients diagnosed with chronic venous disorder, 598 patients (11.12%) were with chronic venous disease and 4,782 patients (88.88%) with venous chronic insufficiency. As we can see the distribution of patient in venous chronic disease and insufficiency is mainly in the group of venous chronic insufficiency, showing that the prophylactic measures, dedicated to patients in venous disease, for preventing the evolution of pathophysiological changes that lead to irreversible changes in the venous system and the installation of the venous insufficiency are insufficient.

In our study the distribution of patient by sex shows approximately equal rates, although data in the literature show an increased rate of chronic venous disease among female patients (fig.5). Worldwide, 10-33% of adult women and 10-20% of men have CVI. In European countries the prevalence among women is even higher, ranging from 20 to 50% (4, 5, 6, 8).

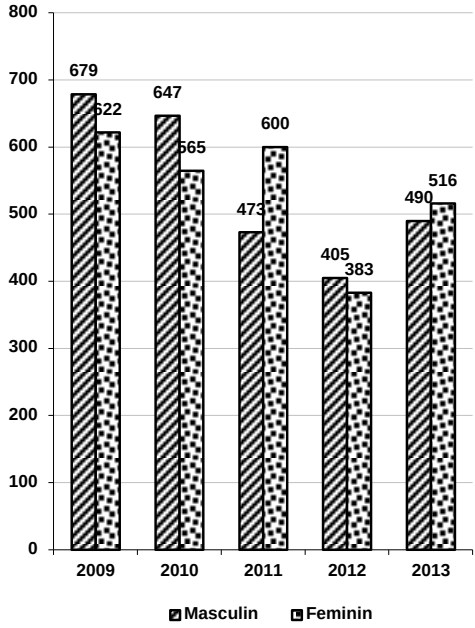

Fig. 5. Number of patients by year and sex

According to the area of residence, most patients (56%) (fig. 6) came from rural areas, probably accounted for by their lifestyle, and also by a delay in seeking medical attention in the early stages of disease, inadequate implementation of primary prevention methods, methods that overlap with general public health education, our data being consistent with the literature data.

As to age group distribution, most patients (44%) were older than 65 years, followed by age group 46-65 years (37%), and

15-45 years (19%), our data being consistent with the literature (fig. 7).

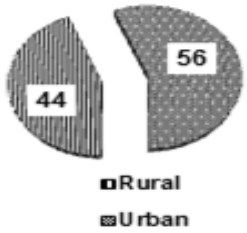

Fig.6. Distribution of patients by area of residence

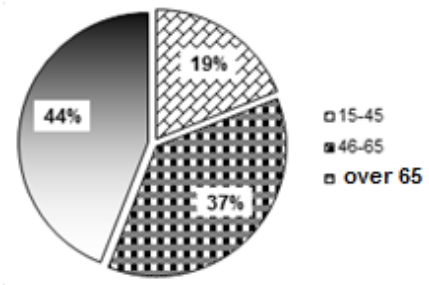

Fig. 7. Age-group distribution of CVD patients

The following predisposing and aggravating factors were identified: genetic predisposition, history of vein thrombosis, obesity, smoking, diabetes, etc.

Given the data resulting from the epidemiological study and their distribution by clinical forms of the disease according to CEAP staging, we focused on patients with CVD CEAP class 6, patients with severe complications, with a major impact on their quality of life, but also on the costs for the healthcare systems, which are being very high.

One of the serious complications of CVD CEAP class 6 is the infection of ulcerative lesions with various pathogens. In descending order of frequency, the main pathogens incriminated in ulcer infections were *Staphylococcus aureus*, *Pseudomonas aeruginoasa*, and methicillin-resistant *Staphylococcus aureus* (MRSA), order maintained throughout the 5 years of study (fig. 8).

Referred to resistance to antibiotics, gentamicin comes first, followed by ciprofloxacin and amoxicillin with clavulanic acid, because of topical and systemic antibiotic abuse, which is a worldwide problem. However, in our study ciprofloxacin proved to be the most sensitive (fig. 9), followed by colistin and teicoplanin (fig. 10).

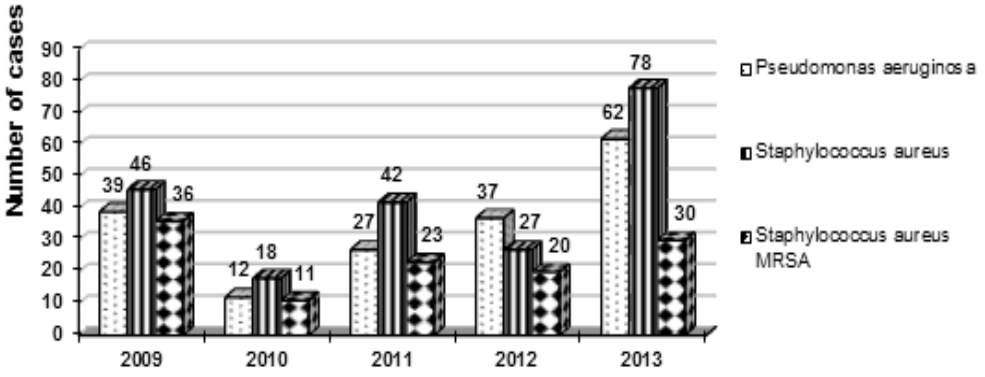

Fig. 8. Most frequent pathogens incriminated in CVI class 6

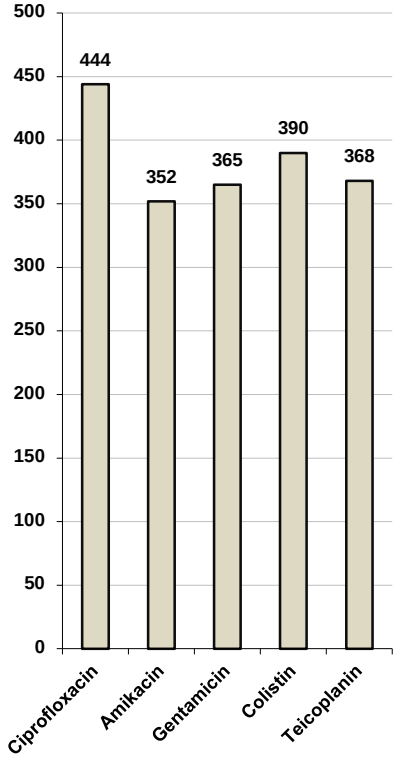

Fig. 9. Antibiotic sensitivity

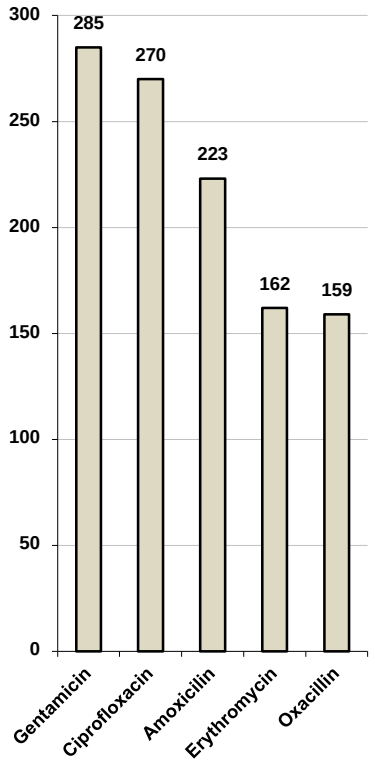

Fig.10. Antibiotic resistance

RESULTS AND DISCUSSION

Data from the present study indicate that chronic venous disorder still raises a serious problem for the healthcare system, even exist a lot of programs dedicated to this disease. Namely, it appears that many patients do not seek medical attention when the disease is in early stages (most patients presenting with classes 3 and 6 according to CEAP classification). The distribution of patients by CEAP classes shows a distribution of the patients mainly in the venous chronic insufficiency (88.88%). Distribution by gender and area of residence was uniform, unlike the worldwide statistical data according to which the disease is more common in females, with a predominance of patients originating from rural environment.

People over the age of 65 were most frequently affected, followed by age groups 46-65 and 15-45 years.

Worrying is the small percentage (11.12%) of patients diagnosed in stage 1 of disease, and also in the group of venous chronic disease (CEAP0-2), these patients being those who can benefit the most from preventive methods, a proper lifestyle, measures that determine a slow progression to advanced disease, and preserve the patient quality of life and ability to work. If prevention programs should be entered correctly if patient education as one of the main goals of primary health care, then we could tip the balance toward those with chronic venous disease.

The main pathogens isolated from ulcerative lesions were *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and MRSA, agents that show resistance to common antibiotics due to their improper use.

CONCLUSIONS

The venous chronic disorder is one of the most common health problems meet in clinical practice, not only in dermatology, but also in general practice, family medicine, internal medicine, cardiology, vascular surgery etc. It is an important problem for the healthcare system because of the very high costs associated with long hospital stay. As this study shows, these problems can be reduced by proper preventive measures, by early identification of the CVD, by correct treatment introduced from the very first stages of the disease.

Detection in early stages, regular and thorough check-ups in patients with genetic predisposition, is the first steps to reducing the incidence and prevalence of CVD in the general population. These issues can be positively influenced by effective prevention methods implemented in the early stages of the disease and by patient education and training.

CVD is currently a very important medical problem that requires multidisciplinary approach (family medicine, dermatology, surgery, internal medicine, etc.), in the literature being regarded as the second most common condition after arterial hypertension among cardiovascular diseases. As the study shows, the prophylaxis and correct treatment of patients in early stages can reduce the percent of patients with chronic venous insufficiency, having a positive impact in the hospitalization rate and costs for the healthcare system.

FIBROMUSCULAR DYSPLASIA OF CARDIAC CONDUCTION SYSTEM ARTERIES IN TRAUMATIC AND NON-NATURAL SUDDEN DEATH VICTIMS AGED 0 TO 40 YEARS: A HISTOLOGICAL ANALYSIS OF 100 CASES

Luminal narrowing by fibromuscular dysplasia of the sinus and/or AV-node artery was found in examinations of unexplained deaths and, in many cases, was considered as the cause of death. There are no data on the frequency of fibromuscular proliferations of arterial walls in heart healthy control groups. In numerous case reports, histological evidence of fibromuscular proliferations of arteries of the cardiac conduction system has been suspected as the cause of death when the autopsy and additional investigations could not determine another cause. Cardiac arrhythmia due to ischemia is proposed to be the lethal pathomechanism. While there is an uniform nomenclature for fibromuscular dysplasia as a disease entity of noncardiac arteries, there are several terms for fibromuscular proliferations of cardiac arteries that are only microscopically detectable, e.g., “fibromuscular hyperplasia”, “occlusive lesions of cardiac conducting tissue arteries”, and “small coronary artery disease”. All of the described alterations of the vessel walls appear as a fibromuscular dysplasia. However, systematic histological investigations have rarely been described. For many forensic pathologists and pathologists, it was clearly evident that fibromuscular proliferations of arterial walls are widely spread in a healthy age group of 0 to 40 years. The assessment of the histological findings in cardiac arteries as a cause of death has to be seen critically since functional causes might also be responsible. Furthermore, the diagnosis of “fibromuscular dysplasia of coronary arteries” should not be confirmed without a macroscopic finding. Since fibromuscular proliferations of arteries of the cardiac conduction system and small coronary arteries occur in 84% in an obviously heart-healthy control group (n=100), these findings should be known to every (forensic) pathologist and anatomist. This might reduce the risk of misdiagnosis. The cause of these fibromuscular vessel alterations is still unclear. Possible hypotheses might be either the consequence of the impact of the bloodstream on small vessel branches or a protective mechanism against luminal extension. The term “fibromuscular dysplasia” should not be used for a thickening of coronary arterial walls that can only be seen microscopically. In addition, Zack et al proposes the establishment of a specific nomenclature for such changes (e.g., fibrous and muscular proliferation of arterial wall tissue) (Zack F, Kutter G, Blaas V, Rodewald AK, Büttner A. Fibromuscular dysplasia of cardiac conduction system arteries in traumatic and non-natural sudden death victims aged 0 to 40 years: a histological analysis of 100 cases. *Cardiovascular Pathology* 2014; 23: 12–16.

RARE COMPLICATION OF THE CERVICAL SPINE TRAUMA – TRAUMATIC ESOPHAGEAL FISTULA: CASE REPORT AND REVIEW OF THE LITERATURE

M. G. Dabija[1,2], B. F. Iliescu[1,2], D. Andronic[2], C. Popescu[2], N. Ianovici[2]

RARE COMPLICATION OF THE CERVICAL SPINE TRAUMA–TRAUMATIC ESOPHAGEAL FISTULA: CASE REPORT AND REVIEW OF THE LITERATURE. (Abstract): **Background and study aims**: Esophageal fistula due to cervical spine trauma is a rare, potentially fatal complication, which changes significantly the treatment and the prognosis of the trauma patient. There is scarce data regarding this associated pathology of cervical trauma and it consists only of isolated cases, most of them being reported as a complication of the surgical treatment. We present the case of a female patient who suffered a fall from a wagon and who was diagnosed at presentation with cervical fracture and esophageal fistula. Patient: A 65 years old female who suffered a fall from a train wagon presented for intense neck pain and bilateral brachial paresis. The MRI exam showed a C6-C7 fracture with bilateral facet dislocation in the context of a degenerative, spondylotic cervical spine. It also showed an anterior fragment from the C7 body, in contact with esophageal adventitia. The patient underwent surgery. **Results:** a C6 corpectomy was performed, with arthrodesis with bone graft and cervical plate fixation. 24 hours after the procedure, the clinical signs of an esophageal fistula appeared and a CT-scan revealed the typical aspects of that complication. The patient underwent a second surgery in collaboration with the general surgeon with a good outcome and complete neurological recovery. **Conclusion:** in the case of cervical spine trauma the imaging exploration has to look for potential signs of lesions to the neighboring vital structures. Although a rare complication of cervical trauma, esophageal fistula represents a formidable complication and requires immediate surgical sanction, the only factor decisive for a good prognosis. **Keywords:** ESOPHAGEAL FISTULA, CERVICAL SPINE SURGERY COMPLICATIONS

Cervical spine trauma represents a devastating event in the life of the patient especially if associated with lesion of the spinal cord. The presence of an associated lesion of the vital structures neighboring the spine makes an already difficult case even more difficult with direct impact on the outcome. Anterior approaches of the cervical spine are largely used for various pathology of the cervical spine and they are considered as safe procedures useful for both decompression of the neural structures and for the inter-body fusions (1, 2). An 8 to 12% rate of complications has been reported by various studies. Esophageal perforation is one of the rarest of all complica-

tions (0.1%) (3). Being so rare there is virtually no individual experience, especially in the treatment which is very controversial and specific to every particular case. The largest series we found is the one reported by Gaudinez in 2000 (3), which included 44 patients admitted in 25 years in a center dedicated for spinal injuries and a second one published by Newhouse who reviewed the data of the Cervical Spine Research Society and he found 22 cases (4). We present our experience with a 67 years old patient operated for a cervical C6-C7 fracture with facet dislocation complicated with esophageal fistula diagnosed in the early postoperative period.

CASE REPORT

A 67 years old woman who suffered a fall from a train wagon, presented in the emergency department of our hospital, complaining of intense neck pain, bilateral brachial paresis, left cervico-brachial neuralgia. Plain radiographs of the cervical spine were made but these showed no obvious traumatic lesions between C1 and C6. Because of the significant clinical picture it was decided to perform a cervical spine MRI which showed a C7 fracture with bilateral facet dislocation C6-C7 and a narrowed spinal canal in the presence of the retropulsed bone fragment from C7 and spinal cord compression with intramedullary hyperintensity on T2 weighted sequences (fig. 1). The patient underwent surgery: anterior corpectomy C7 with the high-speed drill, followed by an inter body fusion C6 to T1 using an iliac bone graft and anterior plate fixation. There were no incidents during surgery. Given that a good reduction wasn't possible without a high risk, we preferred to perform C7 corpectomy.

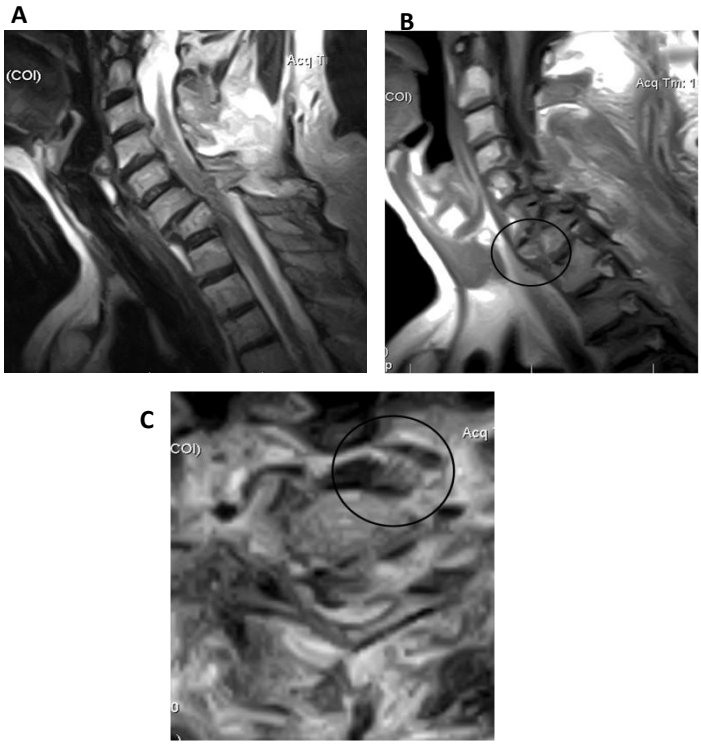

Fig. 1. Preoperative MRI findings showing
A) C7 fracture with bilateral facet dislocation C6-C7,
B) The bone fragment that we found in relation with the site of the perforation,
C) Axial section revealing the bone fragment apparently in relation with esophageal adventitia

Immediately postoperatively the patient performed very well, she was discharged from the intensive care unit, the neck and brachial pain disappeared and she remained with some mild dyparesis. Two days later she developed dysphagia, fever, subcutaneous emphysema of the neck and face, tension at the level of the operatory wound. An emergency CT-scan was performed and it showed the large emphysema and the esophageal defect at the level of the lesion, as well as laryngeal edema (fig. 2).

An emergency reintervention was performed and we found a small bone fragment inserted in the esophagus on his left side (opposite to our operatory view), with a small defect at the adventitia level. Two drainage systems were left in place, a nasogastric tube was inserted and parenteral large spectrum antibiotic therapy (including Imipenem and Metronidazole) was initiated.

The bacteriological results from the operatory wound revealed the presence of gram negative germs sensible at Imipenem. For a week after the second surgery the evolution was good yet, in the eighth day the local inflammatory changes reappeared, with fever and a mild superior digestive hemorrhage and the patient was reoperated. This time an esophageal suture was performed, and a gastrostomy feeding tube was left in place. After the third surgery the evolution was favorable without further complications. The patient remains though, with a permanent gastrostoma.

C) Control CT-scan, at one month, revealing remnant peri-esophageal emphysema

DISCUSSION

Anterior cervical approach, also known as Smith-Robinson approach, is in our days a very well known procedure which is a part of the surgical arsenal of any neurosurgeon dealing with cervical myelopathy or radiculopathy. The complication rates are variable between a medium of 10% and 19.3% as reported by Fountas (5) in a study on 1015 patients (196 complications).

The authors of this study found the dysphagia as the most common complication (9.5%), followed by postoperative hematoma (5.6%), esophageal fistulas being observed in 0.3% of cases. The list of possible other rare, anecdotal complication may be very large, as they are presented in various publications (5, 6, 7, 8), including carotid artery injury, vertebral artery injury, pneumothorax, glossopharyngeal, facial, hypoglosal paresis, lesions of the cervical plexus, epidural hematomas. Concerning the esophageal fistulas, they appear in different statistics in a range between 0% (6) and 1.62% in a study of Elerkay (9) in patients who underwent corpectomies, like our patient. There are not clearly identified predisposing factors but the patients with cervical spine fracture, esophageal diverticula or reflux disease (10), or who have had a corpectomy (9) might have some additional risk. There are not many protective measures, but what we can do is to visualize well and respect the esophagus during high-speed drilling and at the time of the instrumentation and care must be taken to the placement of the internal retractor blade under the *longus colli* muscle.

We know, as surgeons, that even in the most careful procedure, accidents may happened, but it's important to recognize and to react promptly in face of a very rare situation, any delay or hesitation being associated with a poor outcome. Esophageal perforations occurring after a cervical spine fracture or as a complication of the surgical procedure is one of these very rare conditions, but they are potentially life threatening. The management of this extremely rare condition is not standardized and individual surgeon experience is poor. The diagnostic is mainly on clinical basis, the patient complaints are dysphagia, neck pains, subcutaneous emphysema, hoarseness, fever.

We can discover the complication during the operation or the onset can be acute, in the first 24 hours, sub acute, after 24 hours, or delayed, there is a report of a fistula discovered at 10 years (10).

We did not concluded clearly if, in our particular case, the esophageal perforation was traumatic or iatrogenic, but we consider that the most important is not why that happened but what you have to do when that happened. Most of the authors agreed that the treatment is case adapted. If the lesion is discovered during the surgery it is better to suture primary with protection with large spectrum antibiotics and insertion of a nasal-gastric tube.

The fistulas discovered early after surgery, like our case, have to be explored and the operatory field drained, and we consider now that the suture might be an option, because, even in a small defect, like we experienced, the evolution with drainage, esophageal rest with NG tube, and antibiotics (option indicated by many authors), was not very satisfactory and we were forced, finally, to suture.

We had the impression that the perforation was significantly larger when we reopened. In cases of large defects the suture is indicated and some authors recommended reinforcing the closure with

omental, pectoral or sternocleidomastoid flaps (11, 12).

CONCLUSIONS

Esophageal fistula associated with cervical spine trauma is a very rare complication, but the consequences may be tragic, the evolution can complicate with a mediastinitis or septicemia, that can be fatal.

The predisposing factors are not clearly identified, but the corpectomy, instrumentation, spondylotic changes, esophageal diverticula or gastro-esophageal reflux appear to play a role.

We present a case of a perforation discovered in the early postoperative period and our experience in that case make us to advocate an aggressive attitude, so to suture the defect, even it appear to be small.

The great majority of these complications being iatrogenic, we emphasize once again the role of a meticulous dissection, and anyone of us has to think, during the anterior cervical surgery, at this complication which can devastate a perfectly curable patient.

POSSIBLE PROGRESSION OF SUBACUTE LUPUS ERYTHEMATOSUS- CASE REPORT (Abstract): Subacute lupus erythematosus (SLE) is a specific form of lupus erythematosus characterized by prevalently cutaneous manifestations usually with a good prognosis. It is more common in patients aged 15 to 70 years, and there is a female predilection. This form accounts for 10% of all lupus erythematosus cases. We present the case of a 57-year-old male patient diagnosed at age 35 with chronic psoriasiform subacute lupus erythematosus, pathologically confirmed at the Iaşi Dermatology Clinic. At the age of 54 years he had multiple ischemic strokes, followed by deterioration of general status, and at 56 years deep vein thrombosis in the right leg. The patient presented the erythematous-squamous lesions specific to psoriasiform SLE localized both on the upper third of the body and knees and associated with submucosal lesions of the lower lip, oral mucosa and appendages. The patient also presented hypo- and hyperpigmentated atrophic scar-like lesions. Laboratory tests performed during the last two admissions showed the presence of anti-ds DNA and antiphospholipid antibodies, inflammatory syndrome, and nitrogen retention syndrome. Treatment consisted of systemic and local dermatocorticoids and associated medication, emollient lotions and creams with SPF 50+, with slowly favorable progression. The peculiarity of the case lies in the chronic progression without significant systemic involvement for 19 years, and then in 2 years the antiphospholipid antibody syndrome and a shift to systemic lupus erythematosus to occur. **Keywords:** SUBACUTE LUPUS ERYTHEMATOSUS, SYSTEMIC LUPUS ERYTHEMATOSUS, ANTIPHOSPHOLIPID ANTIBODY SYNDROME.

Subacute lupus erythematosus (SLE) is a specific form of lupus erythematosus characterized by prevalently cutaneous manifestations usually with a good prognosis. It is more common in patients aged 15 to 70 years, and there is a female predilection (2). This form accounts for 10% of all lupus erythematosus cases (1).

It is characterized by the presence of two clinical forms: annular and psoriasiform.

The etiologic factors involved in SLE

occurrence:

• Genetic predisposition: more commonly affected were found to be the HLA B8 and DR3 individuals.

• Immunological factors: in 80% of cases there is an association with the presence of SSA antibodies, and in 60% of cases with the presence of antinuclear antibodies. Some patients may also present a C2 complement deficiency.

• The environmental factors involved in the occurrence of subacute lupus erythematosus are represented by exposure to UV radiation, some drugs (thiazide diuretics, calcium blockers, statins, angiotensin converting enzyme inhibitors, Terbinafine, Griseofulvin etc), radiation therapy, PUVA treatment for psoriasis (1, 7, 8, 9).

CASE REPORT

We present the case of a 57 year old male patient from a rural area, ex-smoker and former chronic ethanol consumer (until about 2 years ago), known to have SLE since 1992. His past medical history included many diseases aggravated by tobacco consumption (chronic obstructive bronchopneumonia, pulmonary emphysema, chronic bronchitis caused by cigarette smoking, obstructive arteriopathy of the lower limbs) and cardiovascular diseases (essential hypertension, chronic venous insufficiency, strokes, deep vein thrombosis).

The patient was known to have sub acute lupus erythematosus since age 35, pathologically confirmed both in 1994 and in 2011, with chronic progression due to incorrectly applied treatment, drug regimen (Prednisone), and therapeutic non-compliance related to chronic ethanol consumption. After 19 years of sub acute lupus erythematosus evolution, at the age of 54 years the patient had multiple strokes, resulting in general health deterioration. The patient did not come to the Dermatology Clinic for clinical, biological and therapy reassessment visits for 2 years. At age 56 years he developed deep vein thrombosis of the right leg.

Physical examination revealed a vicious position of the lower limbs with genu valgum, atrophy of the left leg, related to left hemiparesis. Pulmonary auscultation revealed sibilant and ronflant rales disseminated on both pulmonary areas.

Dermatological examination revealed erythematous-squamous plaques, well-delimited, with irregular contours, covered by gray scales, multilayered, adherent, and postlesional achromic plaques, well-delimited, with irregular contours, located on the anterior and posterior thorax, upper limbs, knees, face (fig. 1).

Fig. 1. Cutaneous erythematous-squamous and atrophic lesions on the arm

The patient presented both mucosal and submucosal changes consisting of erythematous plaques covered by scales on the lips and erosions surrounded by inflammatory halo on the hard palate, near the molars and changes in skin appendages, nail plate with rough, rugged, irregular, matte surface, with white surface areas, some of them with subungual keratosis deposit, periungual erythema and hyperkeratotic cuticles (fig. 2).

Fig. 2. Ungual and periungual changes

Laboratory tests revealed blood glucose levels within normal ranges until 2013, when a diagnosis of diabetes mellitus type 2 is made and insulin treatment is initiated. Another finding was an alteration of renal function with the occurrence of nitrogen retention and hepatic cholestasis phenomena. Immunologically, the patient had high anti-dsDNA antibody levels upon admission in 2011 and June 2013 which returned to normal with adequate treatment. Although SSA antibodies are specific to subacute lupus erythematosus, the patient showed levels within normal ranges. On two occasions he had high levels (twice the normal value) of antiphospholipid antibodies.

Pathological examination showed a skin fragment with uneven epidermis, with atrophic areas covered by a crust of orthokeratosic keratin associated here and there with plugging of follicular ostia. The granular layer was prominent and papillary dermis contained moderate lymphomonocytic inflammatory infiltrate with isolated appearances of interface dermatitis and rare Civatte bodies (fig. 3). The histopathological appearance corresponds to a lupus lesion.

Direct immunofluorescence was performed on both lesional and healthy skin, and immunnoglobulin G and fibrinogen deposits in the basement membrane were found (fig. 4).

Cardiology consultation detected non-obstructive hypertrophic cardiomyopathy associated with parietal kinetic disorders on echocardiography and left axillary pachypleuritis on chest radiograph.

Given the presence of nitrogen retention a nephrology consultation was requested. The ultrasound showed small kidneys and in association with the absence of proteinuria, the laboratory changes were interpreted in the context of an antiphospholipid antibody syndrome-related ischemic nephropathy.

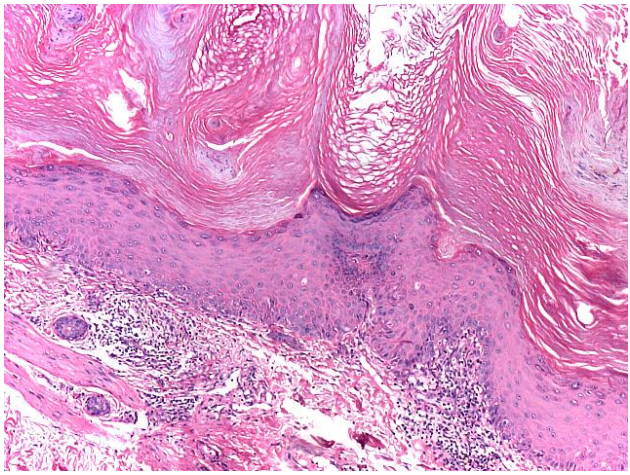

Fig. 3. Histopathologic appearance

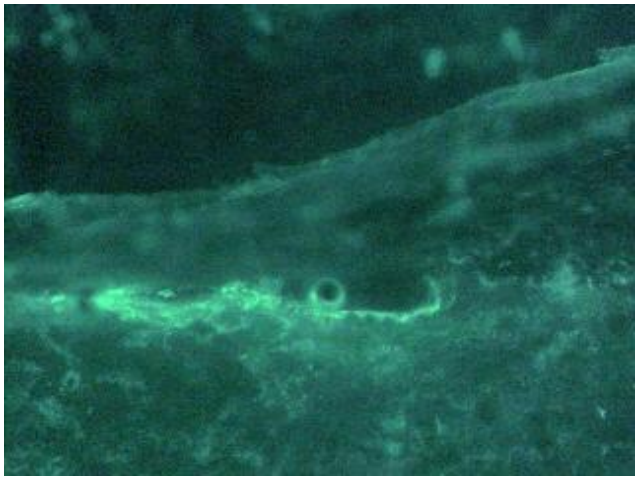

Fig. 4. Presence of IgG in the basement membrane

Based on physical examination and laboratory test results a diagnosis of psoriasiform subacute lupus erythematosus progressed to systemic lupus erythematosus associated with antiphospholipid antibody syndrome was made.

Arguments in favor of subacute lupus erythematosus progression to systemic lupus erythematosus are related to the biological changes, consisting of nitrogen retention, inflammatory syndrome, and presence of anti-dsDNA antibodies, association of antiphospholipid antibody syndrome, multiple strokes, and deep vein thrombosis. Systematization of lupus erythematosus is also demonstrated by kidney and cardiac involvement, positive direct immunofluorescence both on healthy and lesional skin, and therapeutic test, the renal function improving with adequate cortisone therapy.

The therapeutic scheme included topical

dermatocorticoids associated with mechanical and chemical photoprotection, and systemic treatment with Prednisone 15mg/day in combination with Imuran 50mg/day, oral anticoagulant and treatment of associated disorders. Under treatment the evolution was slowly favorable, the patient requiring periodic clinical and biological monitoring.

DISCUSSION

Subacute lupus erythematosus is a form of lupus erythematosus characterized by annular or psoriasiform skin lesions located above the waist (neck, trunk, external aspect of the arms) (7, 8).

Patients with SLE present criteria for systemic lupus erythematosus: photosensitivity, arthralgia, serositis, kidney disease, serologic abnormalities. 50% of SLE patients progress to systemic lupus erythematosus (2).

A study conducted in Philadelphia - USA concluded that of the population of patients with cutaneous lupus erythematosus most do not develop systemic lupus erythematosus, and those who progress to this condition require medium to large doses of dermatocorticoids and immunosuppressive drugs because the systemic manifestations are not significant (10). It was also found that there is an average of 8.03 years between the diagnosis of cutaneous lupus erythematosus and the progression to systemic lupus erythematosus (10).

A study of 44 patients diagnosed with SLE showed the presence of anticardiolipin antibodies in 16% of cases and in 11% the association with antiphospholipid antibody syndrome (3).

Antiphospholipid antibody syndrome is characterized by the production of antibodies against phospholipid binding protein which have a role in coagulation. To make the diagnosis of antiphospholipid antibody clinical criteria were developed (presence of vein thrombosis, pregnancy complications) and laboratory criteria (presence of anticardiolipin antibodies anticoagulant antibodies, elevated anti-β 2 glycoprotein antibodies levels in two or more samples 12 weeks apart) (4).

Depending on the organ affected by thrombus, and the severity of blood obstruction, permanent damage or death can result. The most common clinical manifestations of antiphospholipid antibody syndrome are renal failure and stroke, both due to reduced blood flow to the respective organ. Cardiovascular damage can occur with deep vein thrombosis, deep venous insufficiency and valvular heart disease, and pulmonary damage with pulmonary hypertension and pulmonary embolism. Pregnant women who develop antiphospholipid antibody syndrome may have complications such as miscarriage, preterm birth, preeclampsia (5, 6).

CONCLUSIONS

The presented case is particular due to the fact that psoriasiform skin lesions are located both above the waist and on the knees. Although this form of lupus erythematosus is characterized by the presence of anti-SSA antibodies, the patient had values within the normal ranges at each assessment. The disease had a chronic course without significant systemic involvement for 19 years but because of therapeutic non-compliance, incorrect administration of Prednisone treatment, chronic ethanol consumption, and disregarding photoprotection the patient developed systemic lupus erythematosus associated with antiphospholipid antibody syndrome.

THE PARTICULARITIES OF TREATMENT FOR PATIENTS COINFECTED HIV/TB

In 2012, globally, 13% of people who developed TB were HIV positive. Antiretroviral therapy (ART) reduces morbidity and mortality from TB and reduces by 65% the risk of developing the disease. But, against initiating ART in patients with TB treatment pleads the development of immune reconstitution inflammatory syndrome (IRIS), pharmacological interactions and the large number of pills administered. Influence of the time interval between initiation of antiretroviral therapy (ART) and initiation of treatment for tuberculosis (TB) on patients co-infected HIV/TB has been the goal of many prospective and retrospective studies. CAMELIA study in Cambodia showed that initiating ART within two weeks of starting TB treatment improved survival in severely immunosuppressed patients (CD4 T cells <50/μL). STRIDE global survey and study SAPIT South Africa have shown a decrease in mortality when ART is initiated at the beginning of TB treatment versus initiation at the later stages or after completion of TB therapy. In another retrospective study, Han and collaborators showed that mortality was higher for those diagnosed with TB during ART, but did not reveal differences in prognosis for patients with ART initiation in less than 90 days after starting treatment for TB and those whom ART was initiated late or not started. Based on the results of these studies, guidelines World Health Organization recommends that initiating ART should be made as soon as possible within the first 8 weeks after beginning TB treatment or within 2 weeks for severely immunosuppressed patients.World Health Organization. Global tuberculosis report 2013 (Han Sh, Zhou J, Lee M *et al*. Prognostic significance of the interval between the initiation of antiretroviral therapy and the initiation of anti-tuberculosis treatment in HIV/tuberculosis-coinfected patients: results from the TREAT Asia HIV Observational Database. *HIV Med*. 2014; 15(2):77-85).

THREE SYNCHRONOUS PRIMARY PELVIC CANCERS – A CASE REPORT

M. E. Căpîlna[1], Simona Cristina Rusu[1], B. Szabo[1], Cristina Marian[2]

THREE SYNCHRONOUS PRIMARY PELVIC CANCERS – A CASE REPORT (Abstract). The occurrence of synchronous primary gynaecologic malignancies is a relatively common event. However, the occurrence of three different pelvic cancers is very rare. In this report, we describe the clinical, surgical and pathological findings of a patient with synchronous primary malignancies of the fallopian tube, endometrium and sigmoid colon. To our knowledge, it is the first case described in the literature with such an association of primary synchronous cancers. **Keywords**: SYNCHRONOUS, CANCER, GYNAECOLOGICAL, ONCOLOGY, ENDOMETRIAL, ADNEXAL

Synchronous occurrence of endometrial and adnexal (ovarian or tubal) cancer in female genital tract is a well known event in gynaecological oncology. They may indicate either metastatic or independent neoplasms and the clinical or therapeutic implications and prognosis are very different in each occasion. Compared to metastatic dual cancer, two simultaneous primary cancers are relatively rare and can be easily recognized if the histologic types of each cancer are different. Even more, the occurrence of a pelvic third cancer is an extremely rare event.

The aetiology of synchronous malignancy is uncertain but it has been postulated that embryological similar tissues of the female genital tract may develop synchronous neoplasms when simultaneously subjected to carcinogens(1,2).

Recently, we experienced three primary cancers occurring in both tubes, endometrium and sigmoid colon with three different histologic patterns. This case, along with the diagnosis and the treatment of synchronous female genital malignancy, will be briefly reviewed.

CASE PRESENTATION

In April 2013, a 61 years old white female, gravida 1, para 0, was referred to our clinic with the diagnosis of endometrial cancer and a possible synchronous ovarian cancer. She was menopausal since age of 50 and she described a vaginal bleeding started 3 months before. Her past medical and surgical histories were relatively unremarkable, but her family history revealed a duodenum cancer for her mother, a colon cancer for her father and a stomach cancer for her grand-father. A clinical and ultrasound examination in March 2013 revealed

the uterine origin of bleeding, a normal volume uterus but with a 18 mm thick endometrium with a polyp-like image without apparently myometrial invasion and multiseptated, 111x97x90-mm mass having both solid and cystic components in the right ovary, suggesting malignancy ; the left ovary looked normally. A pelvic computed tomographic scan confirmed the existence of the previously mentioned multiseptated cystic right ovarian mass and minimal ascites in the pelvic cavity. In addition, there were no abnormal findings in the abdominal cavity and thorax, with no extraperitoneal enlarged lymph nodes. She underwent in April 2013 a diagnostic uterine curettage under anesthesia in a private hospital, revealing a grade 3 endometriod adenocarcinoma of the endometrium. The CA-125 was elevated 141.8 U/ml. Routine blood test investigations were normal. The clinical diagnosis was stage IA, grade 3 endometrial carcinoma and a synchronous (primary or metastatic) ovarian cancer.

At laparotomy, a right adnexal tumour involving both tube and ovary, of 11x10x9 cm, but mobile, with smooth surface and both solid and cystic parts was discovered. The frozen section revealed malignant tissue. There was a small amount of ascites in the abdomen. The left ovary and the uterus appeared normal. On the sigmoid colon, a tumour producing bowel stenosis and a retraction of the serosa, very suggestive for malignancy, was discovered. We performed a total abdominal hysterectomy with bilateral adnexectomy, pelvic and paraaortal lymphadenectomy, total omentectomy, appendectomy, recto-sigmoid colon resection (about 20 cm) and peritoneal biopsies. The whole procedure lasted 275 minutes. There were no intraoperative complications. The postoperative recovery was uneventful, and she was discharged home after hospitalisation for 9 days.

The final pathology report described a high-grade (MD Anderson grading system) serous adenocarcinoma of right adnexa, involving both tube and ovary; its origin could not be detected, but contained different microscopic patterns: solid, papillary, cystic, micropapillary and glands (fig. 1). In the left tube, a high-grade serous adenocarcinoma involving the mucosal and muscular layer, but without serosal involvement was found. The lefy ovary was microscopically normal. For these reasons, we consider also the right adnexal tumour of tubal origin. The cytology of the ascites revealed malignant cells. There were no metastases into the appendix, peritoneum, omentum and in the 25 from the right and 35 from the left side pelvic and from the 55 paraaortal lymph nodes. Final pathological staging was a high-grade tubal cancer stage pT1cN0.

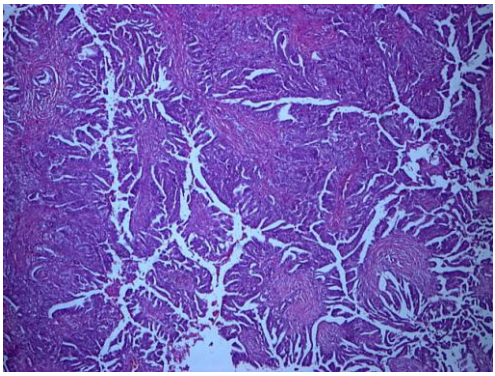

Fig. 1. Solid, papillary, cystic, micropapillary and glands

In the endometrium, an endometrioid type adenocarcinoma grade 3 with mucosal invasion only was found (pT1a grade 3N0) (fig. 2).

The third synchronous cancer was a moderate differentiated adenocarcinoma of

the recto-sigmoid junction with subserosal invasion without metastases in the 17 regional lymph nodes (pT3N0 Dukes-MACB2) (fig. 3).

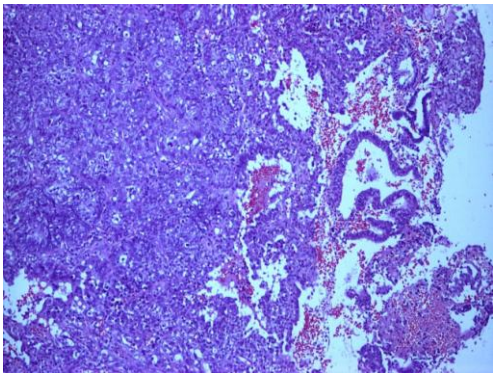

Fig. 2. Endometrioid type adenocarcinoma grade 3, with mucosal invasion

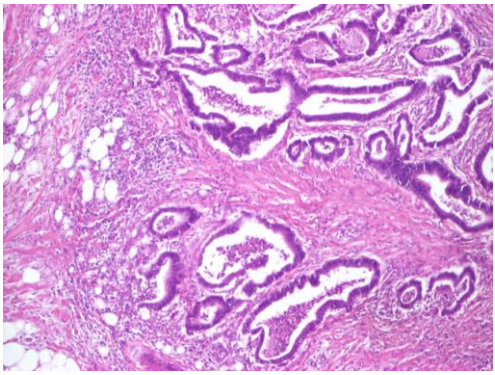

Fig. 3. Moderate differentiated adenocarcinoma of the recto-sigmoid junction with subserosal invasion

The oncology commission in our hospital decided to start the adjuvant treatment focusing on the tubal cancer. The patient started the Carboplatin/Paclitaxel chemotherapy and she is doing well after four courses.

DISCUSSION

The most commonly reported synchronous malignancies were the coexistence of ovarian and endometrial cancers, but genital tract malignancies can arise from more than two anatomical sites, as primary neoplasia. Although the aetiology of synchronous malignancies remains unclear, it has been postulated that the extended mullerian system, comprising ovarian epithelium, fallopian tube, uterus and cervix respond as a single morphological unit to produce primary cancers in different sites. Another theory, which could explain even other sites, suggests that these neoplasms originate in metaplasia occurring in different tissues (4). Till now, limited cases of synchronous primary genital cancers have been reported in the literature, and even less for a third pelvic cancer with an extra-genital origin.

Taking into considerations only 2 cancers out of 3 for our patient (fallopian tube and endometrium), Eisner *et al*(1) described also two synchronous primary cancers of fallopian tube and endometrium, and Atasaver *et al*(8) another 5 sites synchronous cancers involving ovary, both tubes, endometrium and cervix. Our search did not find a similar case in the literature, comprising 3 synchronous malignancies involving 2 genital sites (tube and endometrium) and another pelvic extra-genital one with different embryologic origin (sigmoid colon).

Our pathologic findings fulfilled the conditions described previously for identification of primary synchronous cancers, such as different histologic types (major criterion) or all the following minor criteria: (1) both tumours confined to primary sites; (2) no direct extension between tumours; (3) no lymphvascular tumour emboli; (4) no or only superficial myometrial invasion; and (5) distant metastases (5, 6, 7).

Simultaneous detection of malignancy

in different organs challenges the clinicians and pathologists to make correct diagnosis and arrange proper management (8). Appropriate therapy for synchronous cancers must be planned individually. Different parameters such stage, grade, extension, tumour resection margins, etc should be taken into consideration. As a consequence, our oncology staff decided for this special case that most aggressive tumour necessitating first line adjuvant treatment is the high-grade serous adnexal adenocarcinoma.

NEWS

THE PROTON PUMP AND INFLUENZA INFECTION

Influenza virus A is responsible for epidemic and pandemic flu favored by a high genetic variability. For obtaining infection control, the scientists developed new strategy that target essential viral needs such as viral dependence on cellular glucose. Initiation of viral replication by releasing the viral genome into the host cell cytoplasm is dependent on the acid pH of the endocytosis vesicle. This pH is maintained by a pump proton cell ATP-dependent. The cell uses the glucose as a source of ATP. Using culture cells, the researchers Kohio and Adamson show that higher glucose concentrations into the host cell, increased viral replication, the cells treatment with glycolytic inhibitors decreased viral infection and addition of extracellular ATP restored infection. In these processes, the vacuolar ATPase proton pump had a central role. These findings suggested that influenza infection could be controlled by altering glucose metabolism (Kohio HP, Adamson AL. Glycolytic control of vacuolar-type ATPase activity: a mechanism to regulate influenza viral infection. *Virology*. 2013; 444(1-2):301-9).

EFFECTS OF SOME DOPAMINE AGENTS ON MODULATION OF MEMORY PROCESSES PERFORMANCE IN RATS

Gabriela Rusu, Mihai Nechifor, Catalina Elena Lupusoru, Liliana Tartau
University of Medicine and Pharmacy "Grigore T. Popa"-Iasi
Faculty of Medicine
Discipline of Pharmacology-Algesiology

EFFECTS OF SOME DOPAMINE AGENTS ON MODULATION OF MEMORY PROCESSES PERFORMANCE IN RATS (Abstract) Apomorphine is a potent dopamine receptor agonist which has been used as a neuro-protective agent in the treatment of Parkinson's disease. SCH-23390 is a synthetic compound that presents selective D1 dopamine receptors antagonist activity and possesses pharmacologic effects similar to standard antipsychotics. **Aim:** Experimental researches on the effects of two substances acting on dopamine receptors on the cognitive processes in rats. **Material and methods:** The experiment was carried out on white male Wistar rats (150-200g) divided into 3 groups of 6 animals each, treated intraperitonealy with the same volume of solution as follows: Group I (Control): saline solution 0.3ml; Group II (coded APO): apomorphine 2mg/kbw; Group III (coded SCH): SCH-23390 0.3mg/kbw. Working memory was assessed using the radial-arm maze. The following measures were recorded: the number of entering an arm containing food, but previously entered (working memory errors); the number of entering an arm that was not baited (reference memory errors); time taken to consume all five baits and the number of arms entered until a repeat entry was made (entries to repeat). The data were presented as mean +/- standard deviation and significance was tested by SPSS Statistics for Windows version 17.0 and ANOVA method. Experimental protocol was implemented according to the recommendations of the "Grigore T. Popa" University Committee for Research and Ethical Issues. **Results:** In our experimental conditions dopamine agonist apomorphine produced significantly ($p<0.05$) more novel choices in the first eight-arm entries than the saline vehicle. The animals treated with apomorphine entered significantly ($P<0.05$) more arms compared to the control group. D1 receptor antagonist SCH-23390 induced a significant decrease ($p<0.05$) in the number of working memory errors (elements relevant for short-time memory quantification) and average time taken to consume all five baits ($p<0.05$), but did not modify the number of reference memory errors (for long-time memory quantification) compared to the control group, suggesting a short-time memory retention enhancement and an improvement of discriminative spatial learning. SCH-23390 administration resulted in a not quite significant increase in the number of entries to repeat compared to control rats. **Conclusions:** The administration of apomorphine also increased the search efficiency in total arm entries, suggesting that it facilitates the response in the test session of secondary reinforcement, more than rewarding, effect combined with a lack of discrimination. Our research revealed that D1 receptor antagonist SCH-23390 influenced short-time memory, without affecting long-time memory of experimented animals. **Keywords:** APOMORPHINE, SCH-23390, RADIAL ARM MAZE, COGNITIVE

Dopamine is a neurotransmitter with an important role in forming long-lasting memories for some time, especially in episodic memory. Literature data show that dopamine receptor stimulation may be detrimental to the spatial working memory functions in lab animals (1, 2).

Apomorphine chemically designated as 6aβ-Aporphine-10,11-diol hydrochloride hemihydrate, is a non-ergoline potent dopamine receptor agonist which has been used as a neuro-protective agent in the treatment of Parkinson disease (3).

(R)-(+)-7-Chloro-8-hydroxy-3-methyl-1-phenyl-2,3,4,5-tetrahydro-1H-3-benzazepine hydrochloride derivative SCH-23390, a synthetic compound acting as a selective, high-affinity antagonist of D1 receptors, possesses pharmacologic effects similar to standard antipsychotics (4).

MATERIAL AND METHODS

Male white Wistar rats (150–200g) were used in the study. Animals were housed in plastic cages in an animal room maintained at 23 ± 1°C on a 12-hour dark cycle (light period, 07:00 – 19:00).

Animals received water *ad libidum* and were maintained at 85% of their free feeding weight by controlling the amount of their single daily meal 45 minutes after the experimental session. Before the experiment, rats were placed on a raised wire mesh, under a clear plastic box and allowed 2 hours to acclimate to the testing room.

The animals were divided into 3 groups of 6 subjects each, and treated intraperitoneally as follows:

Group I (Control): saline solution 0.3ml;

Group II (coded APO): apomorphine 2mg/kbw;

Group III (coded SCH): SCH-23390 0.3mg/kbw.

The used drugs, apomorphine, SCH-23390 (Sigma-Aldrich Chemical Company), were dissolved in 0.9% saline, prepared just before use. All drugs were injected intraperitonealy in a constant volume of 1 ml/kg body weight.

The hypothesis that dopamine receptor subtypes are involved in mediation of cognitive pathways is based on a number of experimental reports indicating various activities of different dopamine agents in spatial learning and memory.

To directly prove this hypothesis we investigated the effects of dopamine agonist apomorphine and selective D1 receptor antagonist SCH-23390 on rat memory performance in radial arm maze, a test designed to evaluate lab animals memory processes performances. This standardized test is used as a tool for assessing the neurobehavioral characteristics of memory processes based upon spatial cognition. The substances were administered one hour before the beginning of a behavioral session.

The radial eight-arm maze device consists of central platform (30cm in diameter) elevated from the floor with eight arms (10x80cm) extending radially. The black Plexiglas maze is mounted on an adjustable height tripod (up to 1m). Each arm has lateral walls higher on the proximal side of the arm than on the distal one. On the distal end of each arm, a detachable recessed cup can be installed or replaced by covered up. Food cups for the reinforces were located near the end of each arm.

The design of this device ensures that after checking for food at the end of each arm the animal is forced to return to the central platform before making another choice. The rat always has eight possible options.

After initial acclimation to the laboratory environment there were two daily sessions of 5 min each in which the rat was placed on the maze without bait in the arms. The subject was then trained to run down a single arm to obtain a piece of cheese as the bait. The animals were assigned to learn either the place task or the cue task. Before each session each of the arm was baited with a reinforcer (piece of cheese), placed in a food cup at the end of the arm. The animal was placed on the central platform of the device, allowed to move freely about the maze, and a digital timer was started for a 5 min period of time.

All eight arms of the maze were accessible but four randomly selected were baited.

The arms were not re-baited during the session. Entries into arms previously entered were counted as errors. The session continued until either the animal entered all eight arms or 5 minutes elapsed. The maze was cleaned between trials.

The following measures were recorded: number of novel arms entered during the first eight choices on an un-baited eight-arm maze as well as the total number of arms entered during 5 min, the number of entering an arm containing food, but previously entered (working memory errors); the number of entering an arm that was not baited (reference memory errors); time taken to consume all five baits, and the number of arms entered until a repeat entry was made (entries to repeat). Facilitation of efficient search behavior required an increase in the number of novel arms entered in the first eight choices, rather than simply an increase in total arms entered during the trial.

A camera set above the maze and connected to a monitor in a neighboring room was used to allow us to score behavior without disturbing the animals. All trials were videotaped and subsequently analyzed by a trained observer who was blind to the treatment condition.

Data for each measure were evaluated separately by analysis of variance for repeated determinations. Results were expressed as arithmetic mean ± SD and represented graphically. All values were processed using SPSS for Windows version 17.0 and ANOVA method. P- values less than 0.05 were considered statistically significant compared with those of controls.

Experimental protocol was implemented following the recommendations of the "Grigore T. Popa" University Committee for Research and Ethical Issues guidelines for handling and use of experimental animals, according to the ethical standards of the European Community.

Each animal was used once only and the duration of the experiments was kept as short as possible. For ethical reasons, all the animals were sacrificed at the end of the experiment.

RESULTS AND DISCUSSION

In our experimental conditions apomorphine administration significantly influenced the data of radial arm maze test compared to control group.

Intraperitoneal injection of dopaminergic agonist apomorphine had an evident effect on increasing search efficiency. It produced significantly ($p<0.05$) more novel choices in the first eight-arm entries than either the saline vehicle.

Statistical analysis showed that animals treated with apomorphine consistently entered significantly ($p<0.05$) more arms compared with the control group.

In the behavioral experimental model

used, D1 receptor antagonist SCH-23390 induced a significant decrease ($p<0.05$) in the number of working memory errors (elements relevant for short-time memory quantification) and average time taken to consume all five baits ($p<0.05$), but did not modify the number of reference memory errors (for long-time memory quantification) compared to control group, suggesting a short-time memory retention enhancement and an improvement of discriminative spatial learning (fig. 1, 2, 3).

SCH-23390 administration resulted in a quite insignificant increase ($p<0.05$) in the number of entries to repeat compared to control rats.

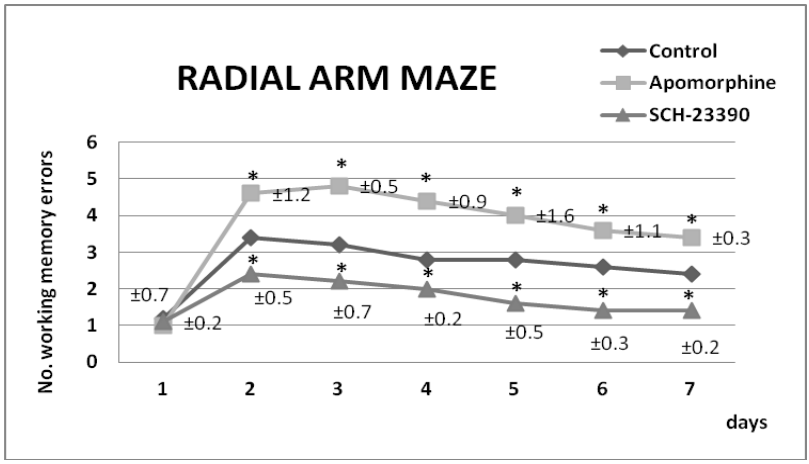

Fig. 1-Effects of apomorphine and SCH-23390 treatment on the number of working memory errors in radial arm maze test. Values were expressed as mean ± S.E.M of the number of working memory errors. *p<0.05, **p<0.01 *vs* control.

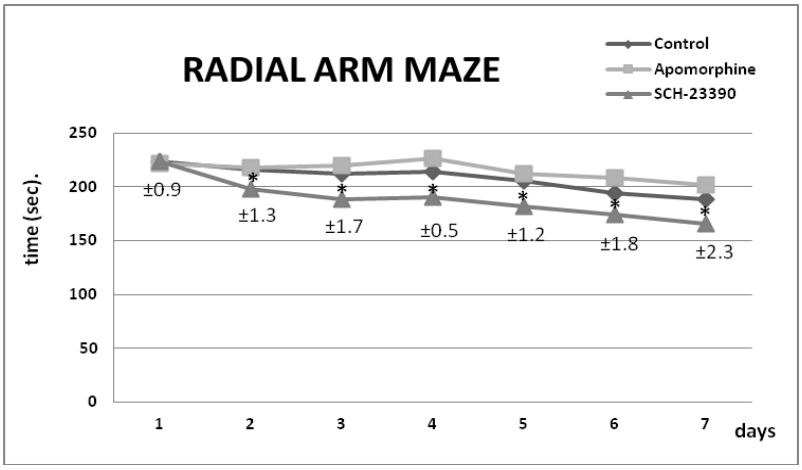

Fig. 2-Effects of apomorphine and SCH-23390 treatment on time (seconds) taken to consume all five baits in radial arm maze test. Values are expressed as mean ± S.E.M of the time taken to consume all five baits. *p<0.05, **p<0.01 *vs* control.

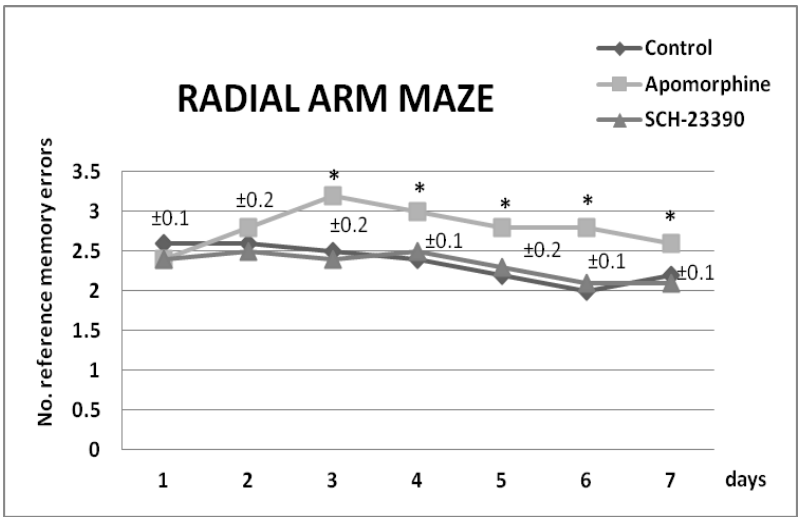

Fig. 3-Effects of apomorphine and SCH-23390 treatment on the number of reference memory errors in radial arm maze test. Values are expressed as mean ± S.E.M of the number of reference memory errors. *p<0.05, **p<0.01 *vs* controls.

Different studies using a variety of approaches suggest that the dopamine pathway may be a key component in modulating activity in the central areas to facilitate behavioral flexibility (1, 10).

The central dopamine receptors, especially D1 receptors in the prefrontal cortex, may be very important for mediating dopamine effects on cognitive functioning (11, 12, 13).

Literature data show that apomorphine stimulates post-synaptic dopamine D_2- type receptors within the caudate putamen in the brain. Different researches revealed that apomorphine improved motor function in an animal model of Parkinson disease and also attenuated the motor deficits induced by experimental lesions in the ascending nigrostriatal dopaminergic pathway in lab animals (14, 15).

Recent cognitive studies proved that apomorphine dose-dependently impaired recognition memory in animals. It is well known the involvement of dopamine receptors in rodent memory and in spontaneous exploration behavior (16).

Experimental studies suggest that SCH 23390 may prevent the spatial working memory disturbances induced by active substances of marijuana, and block the apomorphine-induced stereotypy and methamphetamine-induced lethality in experimental models (17, 18). Also it presented anti-stereotypic, cataleptogenic, and inhibitory effect on amphetamine circling in different laboratory animal species (19).

CONCLUSIONS

The results indicate that facilitation of unconditioned preparatory behavior by dopamine agonist apomorphine applies also to efficient maze search. The administration of apomorphine also increased the search efficiency in total arm entries, suggesting that it facilitates the response in the test session of secondary reinforcement, more than rewarding, effect combined with a lack of discrimination.

Our research revealed that D1 receptor antagonist SCH-23390 influenced short-time memory, without affecting long-time memory of experimented animals. SCH-23390 administration facilitated spatial working memory, as measured by improved choice accuracy in the radial arm maze, when administered to rats.

PLASTIC SURGERY IN 17TH CENTURY EUROPE. CASE STUDY: NICOLAE MILESCU, THE SNUB-NOSED[1]

Daniela Dumbravă, Ştefan Luchian
Romanian Academy
Institute for the History of Religions-Bucharest

CASE STUDY: NICOLAE MILESCU, THE SNUB-NOSED (Abstract). The rising and the existence of plastic and aesthetic surgery in early modern Europe did not have a specific pattern, but was completely different from one nation to another. Colleges of Physicians could only be found in some places in Europe; different Parliaments of Europe's nations did not always elevate being a surgeon to the dignity of a profession, and being a surgeon did not always come with corporate and municipal privileges, or with attractive stipends. Conversely, corporal punishments for treacherous surgeons were ubiquitous. Rhinoplasty falls into the category of what Ambroise Paré named "facial plastic surgery". The technique is a medical source from which many histories derive, one more fascinating than the other: the history of those whose nose was cut off (because of state betrayal, adultery, abjuration, or duelling with swords), the history of those who invented the surgery of nose reconstruction (*e.g.* Suśruta-saṃhitā or Tagliacozzi?), the history of surgeries kept secret in early modern Europe (*e.g.* Tropea, Calabria, Leiden, Padua, Paris, Berlin), and so on. Where does the history of Nicolae Milescu the Snub-nosed fall in all of this? How much of this history do the Moldavian Chronicles record? Is there any "scholarly gossip" in the aristocratic and diplomatic environments at Constantinople? What exactly do the British ambassadors learn concerning Rhinoplasty when they meet Milescu? How do we "walk" within these histories, and why should we be interested at all? What is their stake for modernity? Such are the interrogations that this article seeks to provoke; its purpose is to question (and eventually, synchronise) *histories*, and not exclusively *history*, both in academic terms but also by reassessing the practical knowledge of the 17th century. **Keywords:** HISTORY OF PLASTIC SUGERY, NICOLAE MILESCU, RHINOPLASTY, NASAL SURGERY, PRACTICAL KNOWLEDGE.

1. Nose fractures and nasal reconstruction. Why are we interested in the Antiquity in such cases?

We are interested in the Antiquity because history provides historians with reference documents enabling them to make distinctions and construct a narrative. There is historiographic consensus on the fact that the oldest and most consistent written source for the history of surgery is the *Edwin Smith Surgical Papyrus*, dating back to the Djoser period (c.3000-2500 BC) (1). This source provides us, among others, with a first aetiology of the cases of nose swelling or fracture. Consequently, the novelty of the source resides in the fact that it describes pathologies and provides prescriptions. The papyrus, discovered in Thebes and written in Hieratic, left Luxor in 1862 with Edward Smith (1822-1906), its discoverer, who had purchased it from an anonymous Egyptian merchant (1, 2, 29). Smith donated the papyrus to the *New York Historical Society* before his death. For a short period it was held by the *Brooklin Museum*, before being sent to the *New York Academy of Medicine*, where it remained permanently. The text of this precious papyrus was first translated in 1930 by the Orientalist James Henry Breasted, Egyptologist and founder of the *Institute of Oriental Studies* in Chicago (which is, to this date, a sort of Mecca for Orientalists, devoted mainly to the study of Near Eastern civilisations). Breasted was aided by Dr. Arno B. Lukhardt in the translation of the papyrus, especially with regard to the medical details (29). The Egyptologist James P. Allen, Professor at Brown University, Head of the International Association of Egyptologists and curator of the Egyptian Art Section of the *New York Metropolitan Museum*, provided a second critical edition in 2005, an initiative unequalled so far (1). This source reveals the intense medical activity of Imhòtep, a physician and architect at the court of Pharaoh Netjerykhet or Djoser, the first king and founder of the third Egyptian dynasty (c.2760 BC). Imhòtep would be, at least in theory, the first physician to have indicated the fact that a nasal fracture can be examined, diagnosed and cured. To exemplify, we will quote two of the cases of nasal fracture mentioned in the *Edwin Smith Surgical Papyrus*:

Case 1. *A fracture of the nasal cartilage* (5,10-15). *Title*. Practices for a fracture in the pillar of his nose. Examination and Prognosis. If you treat a man for a fracture in the pillar of his nose, and his nose is flattened and his face is flattened out, while the swelling that is on it is high, and he has bled from his nostrils, then you say about him: "One who has a fracture in the pillar of his nose: an ailment I will handle". *Treatment*. You have to wipe it for him with two plugs of cloth. You have to push tow plugs of cloth wet with oil inside his nostrils. You have to put him on his bed in order to reduce his swelling. You have to set for him stiff rolls of cloth so that his nose is restricted from moving, and treat him afterward with oil and honey dressing every day until he gets well. *Explanations.* As for "the pillar of his nose", it is the bridge and his side of his nose, inside his nose in the middle of his nostrils. As for "his nostrils", they are two sides of his nose penetrating to his cheek, starting at the end of his nose and exciting the top of his nose" (1).

Case 2. *A fracture of the nasal bone* (5,16-6,3*). Title.* Practices for a fracture in

the chamber of his nose. *Examination and Prognosis*. If you treat a man for a fracture in the chamber of his nose and you find his nose crooked and his face flattened, while the swelling that is on it is high, then you say about him: "One who has a fracture in the chamber of his nose: an ailment I will handle". *Treatment.* Set it back in its proper place. Wipe for him the inside of his nostrils with two strip of cloth until every eel of blood that is knotted inside his nostrils comes out. Afterward, you have to push two plugs of cloth wet with oil into his nostrils. You have to set for him two stiff rolls of cloth bandaged on it and treat <him> with an oil and honey dressing every day until he gets well. ***Explanations***. As for "a fracture in the chamber of his nose", it is the middle part of his nose down to where it ends between his eyebrows. As for "his nose crooked and his face flattened", it means that his nose is awry and very swollen all over, and his cheeks likewise, so his face is flattened out from it and is not in its right form, because every sinus is distorted with swelling, so his face looks flattened from it. As for "every eel of blood that is knotted inside his nostrils", it is the coagulated blood inside his nostril, similar to the eel that exists in the water" (1).

The structure of Imhòtep's "medical chart" is remarkable in terms of its accuracy, synthesis and solutions: it specifies the name of the disease, defines the pathology, establishes the diagnosis, prescribes the treatment and, finally, offers practical explanations (17, 29, 32). Also remarkable is the distinction between the upper fracture of the nose and the conditions associated with the nasal cavities, more precisely, the deformations at cartilage level, as well as the different treatment approaches. As a common denominator, the concern for the patient constitutes a priority, as evidenced in the medical indications themselves, as well as in the very fact of their systematic recording. For a physician, as well as for the patient, medical prescriptions were of outmost importance.

As far as historians and philologists are concerned, the typology of the text, the author and the event itself are major landmarks. The source also provides an area of interference between two completely different worlds, namely physicians and historians, retracing the ancient approaches to pathology: types of treatment, medical supplies, position towards the patient, and typology of medical chart. For instance, among the instructions referring to the upper nose fracture, the document mentions the use of linen cloths, useful in performing the haemostasis but also during the first steps in stopping the bleeding. Moreover, linen cloths, dressed in a good lubricant such as oil, once introduced in the two nostrils and positioned as high as possible, stop the haemorrhage. In the case of fracture, the deformed nosed can be bandaged with oil and honey. The two relatively stiff rolls inside the nose will be supported with the patient's hand, while the physician handles nasal bleeding or removes the blood coagulated inside the nostrils, respectively in the ears, when necessary. This operation is extremely painful and can impede the patient from speaking(1). Historical exegesis appreciates positively this type of details, since they are clearly distinct from the idea of medicine as assimilated to magical incantations or religious rites. *Edwin Smith Surgical Papyrus* brings to the fore a "rational" medical treatise, as long as the pathology has an etiology, a diagnosis and a treatment. From this perspective, as mentioned above, this papyrus

is the most important document of surgical medicine in the ancient Near Est.

2. *Suśruta-samhitā* and effective nose reconstruction as surgical procedure.

As far as the *tout court* nasal reconstruction techniques are concerned, the first written source on nose reconstruction as a surgical procedure is included in the *Suśruta-samhitā* source in chapter 16.27-31 *Sūtrasthāna*. According to this source, Louis H. Gray explained that the divine physician Dhanvantari (*i.e.*"well-famous"), received the Āyur-Veda from Brahmā trough the successive meditation of Prajāpati and Indra, then taught it to Suśruta and other six colleagues (30). This is a much earlier source than the *Edwin Smith Surgical Papyrus* source, MS. Bower dating back to the Gupta dynasty period (c. IV-V AD). It describes a surgical technique incorporated into one of the first treaties of Āyurvedic medicine (3, 4, 8, 15, 19, 24). The British captain Hamilton Bower discovered this manuscript in 1890 during one of his travels to the Eastern Turkistan, which accounts for the name MS. Bower. The source is considered to date back to the 4th century, approximately a millennium away from a possible original version. Bower offered the voluminous manuscript to the *Asiatic Society of Bengal*. During one of the reunions of the above mentioned Society in Calcutta, the manuscript was exhibited to the public, drawing the attention of Orientalists, especially connoisseurs of the Sanskrit language. A year later, the manuscript was studied by Dr. Augustus Rudolf F. Hoernle (1841-1918), a physician and Indologist of Indo-British nationality and one of the most educated persons in Calcutta Madrasah (31). Calcutta Madrasah is an institution founded primarily for the study of Arab and Persian languages, aiming to a comprehensive understanding of the Koran texts, and which will later introduce the study of exact sciences. Additionally, Calcutta Madrasah is a place where medicine was studied and where medical books and manuscripts were collected (16, 31).

The first studies and translations of the *Suśruta-saṃhitā* treaty were published in the *Journal of the Asiatic Society of Bengal* and, subsequently, in the *Journal of the Royal Asiatic Society of Great Britain and Ireland*. At the same time, Dr. Hoernle started to work on the first translations there. At the beginning of the 20th century, a complete edition translated from Sanskrit into English was prepared by Kunda Lal Bhishagratna. One of the most obvious problems of the translated version, as the reviewers rigorously warn, was related to the fact that the English medical terminology did not always coincide with the homologous Sanskrit vocabulary (29). Thus, it can be noticed that Orientalist studies in Calcutta develop in tune with medical studies at the end of the 19th century and the beginning of the 20th century.

Suśruta and his medical techniques were also adopted in Ancient China and in the Middle Ages his treatise was translated from Sanskrit into Arab (13, 17, 18, 19). During the Renaissance and the Pre-Modern periods, it finally entered Europe (5, 6, 11, 12, 13, 19, 20, 27, 32). The oral tradition was the first channel for the transmission of medical practice, followed by the tradition of widespread manuscripts and the critical editions of *Suśruta-saṃhitā*, which are no less important. As regards the variety of plastic surgery practice, Suśruta provides remedies for conditions associated with the ear lobes and the

lips, in case of excessive swelling. Rhinoplasty remains the most remarkable procedure, considering its secular diffusion and practice. Arion Roşu (1924-2007) an Indologist of Romanian-French nationality explains the connexion between the name of the technique and the technique itself: „Connue sous le nom de 'greffe indienne', pour refaire un nez retranché, cette tehnique comporte une greffe pédiculée à lambeau de joue (*gaṇḍa*), alors que dans la variante moderne de cette opération, révélée à l'Europe à la fin du XVIIIe siècle, le lambeau est frontal" (19).

In brief, the Indian nose reconstruction technique consists primarily in measuring the nose section to be reconstructed; then, a live-tissue section of skin is treated so as to cover the nose, keeping a small pedicle connecting it to the cheek region. The nose section, on which the skin is to be applied, is previously excised (by removing the scar tissue) with a knife. Subsequently, the surgeon carefully sutures the two parts, uplifting the skin and introducing two cylindrical bandages coated in castor oil, directed on the nostrils position, in order to support and shape them. Once the skin is adapted, it has to be powdered with sweet wood or liquorice powder (*Glycyrrhiza glabra*), red sandalwood and barberry powder (*Berberis vulgaris*). Finally, the nose has to be covered in linen and gently, although continuously, padded with sesame oil. When the skin starts to turn uniform, in case the nose is too long or too short, the supporting device (the flat) will be cut in half or modified, as needed (5, 6, 13, 19, 21, 23, 32) (fig. 1).

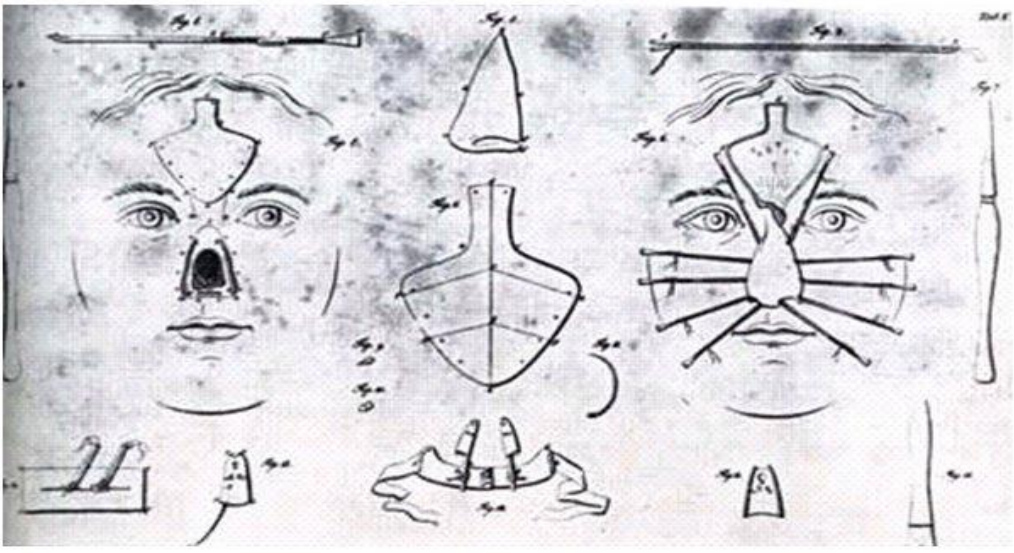

Fig. 1: "Indian flap" for nasal reconstruction apud Sanjay S. (37)

At this point we can be sure that at least the Antiquity provides the distinctions we need in order to differentiate between the virtues of nose treatment in Egypt and those of nasal reconstruction in India. The following conceptual link will refer to the punishments or the various reasons leading to nose mutilation, a link finally leading to the episode featuring Nicolae Milescu, the Snub-Nosed.

3. Punishments and offences.
Why the care for nose integrity?

In Suśruta's India (18), as well as later on, the nose was associated with respect and dignity; this was probably due to the assimilation of body integrity *per se* with the moral norms. Nose mutilation involves dishonour, the stigma of an undesirable sign at the very centre of the face, and automatically means marginalisation and seclusion from the others. Any deviation from the norms of a sexuality controlled by the Brahmin caste and the Vedic/Hindu principles involves a punishment equivalent to the dishonour caused. Similarly, the historian is likely to be familiarised with the punitive measures derived from the Justinian law code, fully functional from late Antiquity to the definitive fall of Constantinople. Crimes related to treason, conspiracy, adultery were not always punished by death, but, just like in India, they could be identified with the image of disgrace. Nose cutting or seclusion in a monastic environment particularly signified political treason or adultery. *Mutatis mutandis*, from pseudo-Aristotle's *Physiognomonikà* or that by Giovanni Battista Della Porta, from Salvadore De Renzi's *Collectio Salernitana* to the screening of the play *Cyrano de Bergerac* by Edmond Rostand or the comedy *Roxanne* (1987) and the famous line: "with that nose you can satisfy two women at the same time", one cannot help distinguishing between *nobilissimus nasorum* and *nasus correspondet praeputio* or virile noses. This is a "detail" that the imagination (scholarly or otherwise) has not ceased to make use of, consolidating the correlation between anatomic characteristics and character or moral features (20). In the 16th century, much more solemnly, the French scientist Laurent Joubert – cited by the historian Luigi Monga (20) – argued that there was not necessarily a correspondence between the proportions of certain anatomical parts: "la portion des membres n'est observée en tous, plusieurs ont une belle trompe de nez qui sont camus du reste et plusieurs camus du nez sont bien appointés du membre principal" (20). We need to remember that, ultimately, most cases of nose mutilation derive from the behaviour of cheated husbands, hence the duel or the nose mutilation punishment. Therefore, a severely punished masculine virility is preferred over a dishonoured femininity killed with stones. But the case of Nicolae Milescu is completely different, though no less exciting.

We will next follow the narrative thread of the chronicler relating the adventure of Nicolae, the Snub-Nosed, stories of Moldavian rulers, then Ottoman chronicles, rumours on unusual subjects from the correspondence of British diplomats at Constantinople, all building, little by little, the story of nose recovery and the luxury of the aesthetic surgery Milescu benefited from in the 17th century at the Prussian court of the Great Elector Frederick William of Brandenburg, most probably under the close supervision of the physician Christian Mentzel.

Power struggle, exile, treason, conspiracy make up, then just like now, the histories of opportunism and of the reigns mediated by the Ottoman Empire, materialising scenarios of political interests. Since historiography does not specify the exact date when Milescu's nose was cut, everything tends to be uncertain. However, after having read exhaustively the polemics between historians, we started looking for the germs of the story in completely different sources than those previously mentioned. For many

scholars in our field, Ion Neculce's chronicle was not a reliable source, which intrigued us even more. Finally, the story of Milescu's nose mutilation could not be sought only in the Romanian Chronicles, which led us to a Turkish chronicle dating back to the 18th century (9, 10). Thus, Naima Targhi briefly gives the following account of: first, the efforts made by Prince Vasile Lupu to redeem his daughter taken hostage by the Ottoman Empire – which revealed his anti-Ottoman views – by promising the damsel's hand to Timush, son of a famous Ukrainian Cossack, Bogdan Zynovii Mykhailovych Khmel'nyts'ki; then, the intention of Eflak *bey*, the Ottoman nickname of Vasile Lupu, to strengthen his army, strong enough reasons to determine the Ottoman Empire to ask for a fabulous sum in return. Finally, Naima Targhi bitterly speaks of a Turkish leader, Bektash *aga*, who facilitated the exchange. In this context, Naima Targhi mentions the initiative of a *devil logothete*, none other than Gheorghe Ştefan (?-1668), one of Vasile Lupu's logothetes, the same who, in the second half of 1653, became involved in the rivalry between the Moldavian Prince and Matei Basarab (1623-1654), which would later undermine his authority.

Why does Naima Targhi consider the logothete (*i.e.* Gheorghe Ştefan) an ungrateful character? Precisely because it was *aga* Matei Basarab who mediated his ascension to the Moldavian throne. George Ştefan is known to be the ruler who employed the copyist Milescu, but the moment of the plot causing the Moldavian scholar to lose his nose was yet to arrive. The 1653 plot against the Moldavian ruler Vasile Lupu fully succeeded, despite the interception of some messages between Matei Basarab and Gheorghe Ştefan or the logothete Costin Ciogolea. Vasile Lupu was aware of conjure, but had to leave the throne. Oddly enough, in 1653, Milescu was in Moldova, supporting Gheorghe Ştefan, despite his links with the Lupu royal family. The whim for power never left Gheorghe Ştefan, not even after he lost, a few years later, the royal seat again; thus, around the years 1659-1660, in similar conditions but with different actors, he tried again to reconfigure the same type of plot, by the same means and for the same purpose: regaining the royal seat of Moldova. This is when Milescu became a part of Gheorghe Ştefan's plan. Neculce wrote about the interception of infamous correspondence, which uncovered the plot, this time with Milescu as a victim, i.e. one of the participants in the plot. As chronicler Neculce mentions, Prince Ştefanită Lupu, a good friend of Milescu's, did not sentence him to death, but handed the executioner his own knife to cut Milescu's nose:

There was a certain boyar, Neculai Milescul, the spatharios (Nicolae the Snub-Nosed Spatharios, by the name of Milescul from Vaslui) from his estate of Vaslui, a learned man and a scholar, who knew many languages: Old Greek, Slavonic, Greek and Turkish. And he was proud and rich, and he would ride in front of the prince, with maces and swords, with harness on the horses. And Prince Ştefăniță treasured and honoured him, placing him at his table and playing cards with him, asking for his advice, for he was a copyist. And then once, for too much good and being too much honoured by Prince Ştefăniță, he set out to write false letters, and sent them in a drilled stick to Prince Constantin "the Old" Băsărabă in Țara Leşească (Poland), urging him to come with the army and remove Prince Ştefăniță from his throne. But Prince

Constantin refused to listen to what was written, and sent the drilled stick and the letters back to Prince Ştefăniță. And Prince Ştefăniță, as soon as he saw the stick and the letters, got angry and asked for Nicolai Milescu to be brought to him, in the small house and had an executioner cut his nose. And Prince Ştefăniță, hastily taking the knife of his belt, he gave it to the executioner to cut his nose. And they did not want to cut his nose with the executioner's knife; they cut it instead with the knife of Prince Ştefăniță himself. Later, Nicolai the Snub-Nosed fled to Țara Nemțească (Germany) and found a doctor, for blood flowed from his cheek and his nose wrinkled, and day after day his blood thickened, and his nose grew back, heeling. And when he returned in the country, under the reign of Prince Iliaș, it could barely be noticed his nose had been cut (11).

Milescu's mutilation presumably took place sometime between 1659 and 1600. This can be deduced from the fact that, in 1659, the chair of Moldavia belonged to Prince Ştefăniță Lupul, and, given the untimely death of the prince, more precisely on the 17th of January 1661, this appears to be the only plausible timeline.

Historical dates, throne succession, intrigues and plots all abound in the history of the Romanian Principalities, but, as regards Gheorghe Ştefan alone, he had the fate of a perpetual wandering prince, asking for support and subsidies from most European countries – a story we will not dwell on here. Milescu left Moldavia in 1660, oscillating between the two Romanian principalities; he was later appointed *kapukahya* at Constantinople (1661-1664), in the service of Prince Grigorie Ghica, the latter being very familiar to the Constantinople environment and a good friend of the princely family Cantacuzino, which also explains the connection between Constantinople and the translation of the *Septuagint* by the Moldavian humanist.

In 1665, Milescu was appointed secretary of the same prince, Grigorie Ghica, and headed in 1666 to Berlin, where he resorted to rhinoplasty. Historical sources do not provide further details on this aspect, but due to the correspondence between two British ambassadors, one in Constantinople, and the other in Tuscany – correspondence published by the British historian Eric D. Tappe and taken over by local historians (34) – it can be inferred that Milescu's snub nose was not overlooked. Why would that be so? The British ambassador, Lord Heneage Winchelsea (1621-1682) wrote a letter dated January 13 - 23, 1667, to his brother in law Sir John Finch, ambassador at the court of the Grand Duke of Tuscany. In this letter, he described in detail Prince Gheorghe Ghica's complaints about an impostor who had betrayed his own master – Grigorie Ghica, none other than his son – and who was using the royal seal in his various escapades in the European courts, taking advantage of the benefits arising from such a recommendation. Finally, as historiography clarifies, Lord Winchelsea mistook the impostor for Constantin Nacul, sent to London in 1666 by Gheorghe Ştefan, a character sharing the same destiny with Milescu: nose mutilation. Despite this confusion, Lord Winchelsea also mentions the mutilation of Milescu's nose and the latter's vast knowledge, recording the episode of the surgery he was subject to in Germany: "He hath a little mark upon the tip of his nose which was cut off by justice for his former knaveries, but in Germany they have so well recovered that deformity that

it is little visible. The name of that person is Nicolai. This you will do well to acquaint the Secretary of State, and cause secret enquiry whether such a person be not at Venice or in Italy"(27).

Sir John Finch (1626-1682) was no common addressee, considering the fact that his main profession was that of physician, Doctor of Medicine, a degree obtained at the University of Padua in 1656. Moreover, Finch was an *extraordinary fellow* of the *College of Physicians of London* and of the *Royal Society*. Undoubtedly, Finch was highly interested in the various types of special surgery, such as, for instance, rhinoplasty. Several sources of medical history indicate the 18th century as the period when the practice of rhinoplasty in Europe becomes known to the British. This may seems rather unrealistic, since the very fact that a British doctor completed his medical studies at a university such as the one in Padua automatically sugests that rhinoplasty was already known in the 17th century and that, in fact, information on nasal reconstruction arrived sometime earlier in England.

In fact, the historian might be tempted to return to the history of the secret medical practices and the European Academies where the study and the practice of surgery was common. In Cambridge, Paris, Leiden, Padua there were the so-called anatomy lecture halls, places designed for carrying out dissections, where the first steps in the study of surgery were made. Together with Italy and England, Germany was part of the barber-surgeon avant-garde; the best-known German surgeon of the time was Wilhelm Fabry von Hilden (1560-1634). However, given the chronological gap, he could not have operated Milescu, nor could have Johannes Schultheiss (1595-1645), the author of a popular treatise on surgery, *Armamentarium Chirurgicum* (1653). Another famous surgeon of Polish origins with comprehensive experience acquired in Germany was Matthaeus Gottfried Purmann (1649-1711), professor of the German doctor Michael Ettmuller (1644-1683). Identifying the surgery practice where Milescu was subject to the nasal reconstruction operation will definitely not be an easy task; we only know that the Medical Academy at the Prussian court in Berlin was represented by Friedrich Hoffmann (1660-1742) and Georg Ernst Stahl (1660-1734). Only Stahl was permanently at the Prussian court in Berlin, elected President of the College of Physicians (*Collegium medicum*), but at the time Milescu resorted to this intervention, Stahl was only 7 years old. Two clues could lead us to believe that the Indian technique of rhinoplasty was known at the court of the Great Elector Frederick William: (i) the fact that he had already been favourable to the idea of organizing trade missions to India, (ii) the presence at the court of the great elector of Andreas Müller (1630?-1694) and his personal doctor Christian Mentzel (1622-1701), both residing in Brandenburg, both familiar with the Asian world and the Chinese language, and both in contact with Jesuit missionaries in the Far East such as, for example, Father Philippe Couplet (1623-1693) (35). Clues of such contacts with the Far East are even traceable in the library of the Great Elector Frederick William, namely in the manuscripts and books briefly described by the Orientalist Julius Klaproth in his *Verzeichniss der Chinesischen und Mandschuischen Bücher und Handschriften der Königlichen Bibliothek zu Berlin*, published in Paris in 1822. The volumes dedicated to Chinese medi-

cine include: *Clavis Medica ad Chinarum doctrinam de pulsibus* and *Medicamenta Simplicia quae à Chinensibus ad usum medicum adhibentur*, both edited with modified titles by Andreas Cleyer and Christian Mentze, but signed by "R. P. Michaelis Boymi Poloni, è Societate Jesu, è Regno Siam, Anno 1658", more precisely, by the Polish Jesuit Michael Boym (1612-1659). (36) The issue of the knowledge of rhinoplasty in mid-seventeenth century Berlin could be summarised as follows: either the Prussian doctor Heinrich von Pfolsprundt spread the method of nasal reconstruction specific to the Branca family, or this information was brought by the Jesuit missioners in China, who provided the Sinologists at the Prussian court with medical information. We tend to believe that the first hypothesis is more accurate, and that the doctor who performed surgery on Milescu in Berlin knew the secrets of nose reconstruction techniques from an autochthonous source. This point of view could give rise to future research, which is likely to map even more precisely the temporal coordinates of the practice of this technique in 17th century Berlin and its influence in other European countries.

4. We do know that Milescu had to choose between the nasal reconstruction of Indian origin and the Tropaean one, practised by the Vianeo brothers in the early 15th century (32). This brings back into discussion the secret surgery practices, more precisely those where nasal reconstruction was assiduously performed. Such practices could be found in central Italy, near Naples and even in some regions of an ethnically composite Sicily, considering the Arab domination and the flow of Sephardic Jews, *genius loci*. We will begin by mentioning the Branca family, since this involves the Prussian doctor Heinrich von Pfolfprundt, the closest to both the secrets of the surgical profession and to Antonio Branca. Pfolfprundt wrote a book in 1460, *Buch der Bündth-Ertznei*, published no sooner than 1868 (5, 32), a volume detailing the technique of nasal reconstruction (fig. 2).

The Vianeo family also contributed to the creation of a most abundant literature in the history of the practice of nasal reconstruction, not only due to their outstanding skills, but also especially due to a revolution in the technique *per se* (clearly different from the Indian technique), a technique they did not describe themselves, but which was *stolen* and disseminated by Gaspare Tagliacozzi (1545-1599) from Bologna by means of his popular treatise: *De curtorum chirurgia per insitionem* (7, 32).

In the summer of 1947, in Tropaea, a large number of surgery professors from the *Università del Mezzogiorno* celebrated the activity and memory of the Vianeo brothers, within the very precincts of the public hospital *Ignazio Toraldo*, putting Calabria on the map of the history of the nasal reconstruction technique. Ironically or not, this is a somehow misleading history, considering the posterity of their discovery. The secret of the reconstructive technique in the Vianeo manner was dis

closed, as mentioned above, in a luxurious Italian Seicento, in medical publications and in illustrations that reveal, step by step, both the technique and the necessary equipment. We mention to this purpose the study *De curtorum chirurgia per insitionem* by Tagliacozzi, a treatise that is fully and freely available in a Frankfurt edition dating back to 1654 (7). We also need to point out that the interest in rhinoplasty manifested in this period was due particularly to syphilis, an incurable disease, inevitably related to the destruction of nose integrity. Tagliacozzi was a surgeon who dealt with the reconstruction of the nose, the ears and the lips, which ensured his notoriety despite the revolution in the rhinoplasty technique made by the Vianeo brothers, Vincenzo, Paolo and Pietro, as a result of a much slower accumulation. A detailed description of the rhinoplasty technique of Tropaean origin was provided by the French doctor Ambroise Paré, similar to the one made by Tagliacozzi in *De curtorum chirurgia per insitionem*: “Il s’est trouvé en Italie un chirurgien qui par son artifice refaisoit des nez de chair en ceste maniere. C’est qu’il coupoit entierement les bords calleux ou cicatrisez du nez perdu comme l’on fait aux becs de lievre : puis faisoit une incision tant grande et profonde qu’il estoit necessaire au milieu de muscle dit biceps, qui est l’un de ceux qui flechist le bras; puis subit faisoit poser le nez en ladite incision et bandoit si bien la teste avec le bras qu’il ne pouvoit vaciller çà ne là; et certains jours après, qui est ordinairement sur le quarantiesme jour, cognoissant l’agglutination du nez avec la chair duduit muscle, en coupoit tant qu’il en falloit pour la portion du nez qui manquoit: en après la façonnoit de sorte qu’il rendoit le nez en figure, grandeur et grosseur qu’il estoit requis, et traittoit ce pendant la playe du bras comme les autres, lors qu’il a d[é]perdition de substance. Et durant les dits quarante jours faisoit user à son malade des panades, pressis et autres viandes faciles à transgloutir, et quant aux rem[è]des desquels il usoit, estoyet de quelques baumes aglutinatifs” (6).

Then, which technique was applied to Milescu during the nasal reconstruction performed in Berlin? Calling back into discussion the description made by Neculce - *and found a doctor, for blood flowed from his cheek and his nose wrinkled, and day after day his blood thickened, and his nose grew back, heeling* – we can infer that

the Suśruta technique was the technique preferred by the anonymous doctor treating Milescu. From the account made in the chronicle, we can infer that the source of the tissue used in the reconstruction of the nose was the cheek (the genian region), that the transfer of live-tissue indicates a surgical strategy, and that the transfer from the genian region to the nasal region was produced successively. In this case, the resemblance between the source provided by chronicler Neculce and the Indian technique, the one according to the *Suśruta-saṃhitā*, seems more plausible: there is a preliminary period, that of manufacturing the pattern of the defect by means of a leaf, followed by drawing and incising the pedicled flap, which is then transferred into the nasal defect to be reconstructed at various successive stages. This delay technique could be what Neculce describes as: *and found a doctor, for blood flowed from his cheek and his nose wrinkled, and day after day his blood thickened, and his nose grew back, heeling* (6).

However, we should further comment that, based on this description, we cannot distinguish whether the genian flap used involved a random movement – thus explaining the delay – or was an axial (nasogenian) flap. In reconstructing the nasal defect, the hypothesis of a nasogenian flap is difficult to support, since two such flaps would be actually needed, bilaterally rotated. A single ampler genian flap would have produced a noticeable deformation of the cheek and, consequently, a visible deformity of the patient's face. The Indian method consists, *grosso modo*, in harvesting the flap from the genian region, as well as alternatively, designing a pedicled frontal flap. The Sicilian method (Branca, Tagliacozzi) prepares the brachial pedicled flap in the medial part of the arm. The technique of the brachial pedicled flap, as it results from European Medieval and Pre-Modern sources, was diffuse and the ways of accessing the information cannot always be known when publications on the topic are missing.

5. Homage to the Society of Physicians and Naturalists in Iaşi.

We may all be familiar with the novella *Secretul doctorului Honigberger (The Secret of Doctor Honigberger)*, by Mircea Eliade, published in 1940, in *Revista Fundaţiilor Regale*. In the magazine *Cuvîntul* of 30 July 1928, Eliade praised the scientific activity and the contributions made to the history of medicine by Dr. Vasile Gomoiu and Valeriu Bologa, having kept a close correspondence with the latter during his stay in Calcutta (1929-1931) (33). In fact, Eliade uses this eulogy on the occasion of the establishment of the first Academic Society in the Romanian Principalities in order to establish a link between the impressive editorial and scientific activity of George Sarton – founder of the journal *Isis*, the first journal devoted to the history of sciences in the United States – and the assiduous activity of the two physicians, Gomoiu and Bologa, members of the *International Society for the History of Medicine* and founders of the studies in the history of medicine in Cluj during the first decades of the 20th century (33). Returning to Eliade's period in Calcutta, the Indologist and historian of religions Eugen Ciurtin argues that Eliade first found out about Johann Martin Honigberger (1795-1869), the Transylvanian Saxon physician from Braşov, by reading the English edition of his autobiography, published in

1852, *Thirty-Five Years in the East*, which was translated and edited in Romanian in 2004 by Polirom publishing house, with an impressive critical apparatus and an introductory study (9).

Eliade-Honigberger or Honigberger-Eliade? In this case, reality precedes fiction; based on clear and convincing historiographical findings, it has become common knowledge that Johann Martin Honigberger existed indeed, that he had an absolutely impressive biography, of which we will briefly mention no more than two details: first, *Thirty-Five Years in the East*, a volume offering a generous description of rhinoplasty in India (8); second, Honigberger, the anonymous contributor to the politico-literary publication *Albina Românească*, a newspaper founded in 1829 in Iaşi by Gheorghe Asachi, shortly before the establishment of the distinguished Society of Physicians and Naturalists.

This is how Honigberger describes the rhinoplasty procedure in the volume *Thirty-Five Years in the East*: "I introduced to our distinguished guests, Col. Wade and Dr. Murray an Akalee or Nahung, whose nose, ears and hands had been cut off by order of Runjeet Sing (he had even deserved the gallows), and whose nose had been so well restored in the mountains that we were all surprised, and confessed it could not have been better done in Europe. As we know, from history, this operation was even in the remotest antiquity, practised by Hindoos; and they formed the nose out of the cuticle of the forehead, which proceeding is now, and always will be the same. In Europe, where cutting off of noses is only in use, in exceptional cases – as when ulceration or other circumstances make it requisite – this operation is usually performed with the cuticle of the arm, and judiciously too, as, according to our custom, the head mostly is uncovered, and a scar on one's forehead, with a new nose on the face, makes rather an ugly appearance; whilst, in the East, the scar remains hidden beneath the turban" (8).

The contribution of the Transylvanian Saxon physician to the knowledge about Asian medicine, flora, fauna and antiquity studies, together with his political and military contributions were often presented in the pages of the *Albina Românească* newspaper, which determined, most probably, the visit of Honigberger in Iaşi, during one of the reunions of the Society of Phhysicians and Naturalists, an event also signalled by the *Albina Românească*, no. IX, 15 May 1838. Returning from Constantinople – he had no knowledge of Nicolae the Snub-Nosed – Honigberger was received with some ceremony, considering the title (prince of Aracan Aureg-Seib of India) as the *Calendarul pentru poporul românesc*, a magazine from Iaşi, chose to announce him, recalling him (with a slight delay) between 1838 and 1861.

As regards Johann Martin Honigberger's visit at the *Society of Physicians and Naturalists*, besides other highly interesting details, the historian would have more to say.

This is where the circle somehow closes: we argue that the history of Asian studies and the study of Oriental languages contribute to strengthening the epistemological space of the history of medicine, offering adventure and erudition as the ingredients of a huge intellectual horizon, encapsulating the memory of alterities and of the history of practical knowledge.

If the mutilation and reconstruction of Milescu's nose stir such a historiographical interest in the analysis of an extremely unusual excerpt from Neculce's chronicle,

which then leads to a partial explanation of an unclear episode in the adventurous life of the Moldavian scholar, then the effort was worthwhile.

3. Cardiovascular Rehabilitation Clinic

MARKERS OF INSULIN RESISTANCE IN A CASE OF LAUNOIS-BENSAUDE SYNDROME (Abstract): Launois-Bensaude syndrome (benign symmetric lipoma-tosis) is a rare disease characterized by symmetric fat deposits localized in the cervical region, shoulders and proximal parts of upper and lower limbs. We present the case of a 63-year-old male who presented the typical location of fatty masses and a history of chronic alcoholism associated with elements defining the metabolic syndrome. The biological profile indicated high-atherogenic mixed dyslipidemia, high basal insulinemia (30 μU/ml), and multiple markers of insulin resistance (Reaven index, lipid accumulation product, homeostatic model, insulin sensitivity index, and modified glycemic curve following oral glucose load). The particularity of the presented case is the discordance between the severity of metabolic disturbances and their clinical expression, raising the question whether this patient's cardiometabolic risk is increased or rather lowered by the association of benign symmetric lipomatosis. **Kewords**: LAUNOIS-BENSAUDE SYNDROME, INSULIN RESISTANCE.

Launois-Bensaude syndrome (benign symmetric lipomatosis, Madelung's disease) is a rare disease of unknown prevalence, characterized by symmetric fat deposits prevalently localized around the cervical region, in the shoulders and proximal part of the arms and legs. The name of this disease is chronologically disputed by Sir Benjamin Brodie (1846), the first who described this deformity, followed by Otto W. Madelung (1888), a German surgeon, his name being particularly related to the disease eponymous with prevalently cervical location ("Madelung's collar or neck"); in 1898, Raoul Bensaude and Pierre-Emile Launois published the first series of 75 cases and provided a full description of the characteristic features of the disease, adopting the term symmetric lipomatosis (1,2).

Middle-aged (30-60 years) males are most commonly affected, developing the characteristic distribution of body fat after at least 10 years of abusive ethanol consumption. The etiopathogenesis of benign symmetric lipomatosis is not fully known, the hypertrophy of malfunctioning brown fat and the decreased activity of mitochondrial respiratory enzymes that may result in lipolytic pathway depression being incriminated. In all these processes, alcohol is a

possible co-factor. The only effective treatment is surgery, through lipectomy and/or liposuction of fat masses (2, 3).

CASE PRESENTATION

A 63-year-ols male from a rural area presented to the Pulmonary Rehabilitation Clinic of the Iasi Rehabilitation Clinic Hospital complaining of dyspnea, mMRC (*modified Medical Research Council*) breathlessness scale grade 2, intermittent productive cough and mild fatigability.

The patient presented to our clinic for entering a respiratory rehabilitation program having a previous diagnosis of moderate chronic obstructive pulmonary disease (COPD), the symptoms of this chronic lung disease being well controlled with inhaled tiotropium18 μg/day. He also presented grade 2 essential hypertension, blood pressure being optimally controlled with amlodipine 10 mg daily.

What drew our attention during physical examination were the pseudotumoral subcutaneous masses: relatively symmetrical, located mainly in the proximal parts of the upper and lower limbs, with a pseudohypertrophic appearance, and under the chin, behind the ear, and in the nuchal region, resembling a Madelung's collar (fig. 1).

Fig. 1. Relatively symmetric fat deposits in the upper half of the trunk and upper limbs

On palpation, multiple mobile and painless small abdominal lipomas, like the masses in the upper body, were detected (fig. 2). Family history revealed that two patient's brothers present a similar appearance; from personal history we found out that the fat masses with a typical location for Launois-Bensaude syndrome developed progressively over the last 20 years. Surgical removal of one mass located behind the right ear that became painful confirmed its benign nature, lipoma, but resulted in local recurrence.

The patient was a smoker (35 pack-years) and had a history of chronic ethanol consumption (70 international units/week, abstinent for about 6 months); clinically, stigmata of chronic alcoholism persisted, represented by retraction of palmar aponeurosis (Dupuytren's contracture), bilat-

eral parotid gland hypertrophy, telangiectasias on the nose and cheekbone, but laboratory tests confirmed abstinence, serum transaminases, gamma-glutamyltranspeptidase and mean corpuscular volume being normal.

Fig. 2. Abdominal lipomas (left) and under the chin (right)

Patient's anthropometric data showed a body mass index of 30.14 kg/m^2, corresponding to grade I obesity, and a pathological waist circumference of 115 cm, measured in standing position halfway between the costal margin and iliac crest line.

The metabolic profile revealed mixed dyslipidemia at high atherogenic risk (total cholesterol = 6 mmol/l, HDL-cholesterol = 0.9 mmol/l, triglycerides = 1.64 mmol/l, LDL-cholesterol = 4.32 mmol/l), normal glucose levels (4.93 mmol/l, and high basal insulinemia (30 μU/ml), indicator of insulin resistance.

Given the presence of basal hyperinsulinemia, we calculated the markers of insulin resistance derived from previous biological and anthropometric measurements (tab. I).

Also a 3-hour 75-gram oral glucose tolerance test was performed (fig. 3).

TABLE I

Markers of insulin resistance

MARKERS OF INSULIN RESISTANCE	RESULTS	COMMENTS
TG/HDL ratio (Reaven index)	4.17	Reaven index ≥ 3,5 indicates insulin resistance (4)
LAP (lipid accumulation product)	82 cm. mmol/l	Lipid accumulation product correlates well with insulin resistance and metabolic syndrome (5)
HOMA-IR (homeostatic model assessment of insulin resistance)	5.33	Values ≥ 2.6 indicate insulin resistance status; ≥ 4 it is considered prediabetic status (6)
QUICKI(quantitative insulin sensitivity check index)	0.29	Low values (< 0.45) suggest insulin resistance ; < 0.3 in diabetics (7)

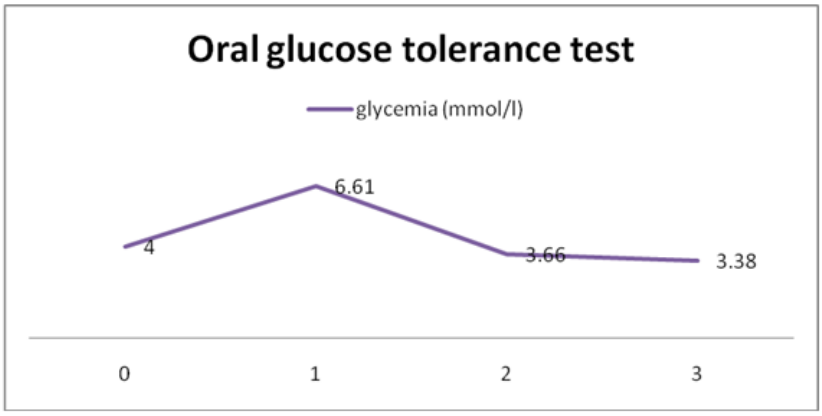

Fig. 3. Evolution of glycemia over the 3-hour 75-g oral glucose load

DISCUSSION

The patient presented a rare disease, benign symmetric lipomatosis, associated with metabolic syndrome, defined in this case by three factors: hypertension, abdominal obesity and low HDL-cholesterol, serum triglycerides being at the limit of diagnostic significance and basal glycemia levels within normal range (8). Simultaneous determination of basal insulinemia and calculation of some markers of insulin resistance (tab. I) revealed frankly pathological values, allowing the assertion of a hyperinsulinemic status associated with insulin resistance.

Remarkable is the discordance between the severity of metabolic disturbances and their clinical expression: the associated pathological conditions (hypertension, COPD) were easily controlled therapeutically and glucose metabolism disturbances were not very obvious. Thus, basal glycemia and the values of oral glucose tolerance test (fig. 3) were normal at fasting or at 2 hours, but prolonged monitoring for three hours revealed a late hypoglycemic dip, result of an abnormal overproduction of insulin in response to glucose load.

The particularity of this case is related to whether the patient's cardiometabolic risk, consequence of the accumulation of risk factors - male, smoking status, hypertension, chronic alcohol consumption, obesity - is increased or rather lowered by the association of Launois-Bensaude syndrome, having in view the mild clinical course despite the severity of underlying metabolic changes?

Review of literature data on Launois-Bensaude syndrome reveals a quite wide phenotypic and clinical variability in this category of patients, ranging from a type of "metabolically innocent" obesity with increased insulin sensitivity by decreased visceral adiposity ascertained by computer tomography (9), to a metabolic picture dominated by insulin resistance, particularly in those patients associating cervical lipomatose deposits and an obstructive sleep apnea syndrome, in its turn generating insulin resistance (10).

The presented case seems to be halfway between these two extremes, but the lack of large studies and validation of any of the models does not allow drawing an indisputable conclusion.

PELTOPHORUM AFRICANUM: ANTIMICROBIAL POTENTIAL AND HEPATOTOXICITY

The antimicrobial activity and hepatotoxicity of *Peltophorum africanum* were evaluated in a study by Okeleye *et al.* Agar well and macrodilution methods were used for antimicrobial activity testing, as well as CellTiter-Blue cell viability assay to assess the toxicity on human liver cells. The results showed both bactericidal and bacteriostatic or fungistatic activity of the extract. The researchers observed good activity against *Plesiomonas shigelloides*. Despite its antimicrobial activity, the extract was toxic to human liver cell lines. Lethal dose at 50 revealed 82.64 ± 1.40 degree of toxicity at 24 hrs, while 95 percentile of cell death dose activity varied between log 3.12 and 4.59. (Okeleye BI, Mkwetshana NT, Ndip RN. Evaluation of the Antibacterial and Antifungal Potential of *Peltophorum africanum*: Toxicological Effect on Human Chang Liver Cell Line. *ScientificWorldJournal* 2013; 2013: 878735. doi: 10.1155/2013/878735).

DOCTOR-PATIENT DIALOGUE – BASIC ASPECT OF MEDICAL CONSULTATION

Isabella Cristina Murariu-Brujbu[1], Luana Andreea Macovei[2]

DOCTOR-PATIENT DIALOGUE – BASIC ASPECT OF MEDICAL CONSULTATION (Abstract): Family medicine is the specialty that provides ongoing primary medical care and improves the health status of the individual, of the family and of the community through preventive, educational, therapeutic and rehabilitation measures. The family doctor often makes the interdisciplinary synthesis, in a flexible manner, either alone or in most cases with interdisciplinary consultation. In the latter case, the family doctor initiates the team work and makes the final evaluation by using the longitudinal follow-up of the disease. The doctor-patient encounter represents the "confrontation" with the greatest moral weight, due to the complexity of the values involved, the status of the doctor in a society, and patient's involvement in decision making. The patient is a person who should be treated with respect, honesty, professionalism and loyalty, whatever the clinical status, severity of illness, mental competence or incompetence. A focus, on an international scale, is represented by the characteristics of a good doctor, family physician included, as the latter is the first link in the network of health services. Each model of consultation varies in a more or less subtle way in priorities assignment, and suggests slight differences regarding the role played by doctor and patient in their collaboration. The qualities of a good family physician include not only the strictly professional competences, that also apply to other medical specialties, but also duties, such as, clearly explaining to patients issues concerning their health, informing them about all the possible preventive measures of diseases, making a diagnosis, initiating and supervising a therapy. Medical responsibility lies at the crossroads between medical science and the conscience of the doctor. **Keywords**: DOCTOR-PATIENT DIALOGUE, MEDICAL CONSULTATION, THERAPEUTIC ACT, PREVENTIVE MEASURES, ANAMNESIS, ENQUIRY.

IMPORTANCE OF THE PROBLEM

The disease represents an unfortunate episode in everyone's life, and it has often many negative effects on the entire body. Patient's concern, the fear induced by the disease, but also inappropriately by the family and entourage, sometimes leads to a deep depressive state. In such circumstances, through his conduct, the family doctor has the duty and the professional and moral obligation to create an optimal cooperation climate throughout the period of investigation and care, right from the first contact. This cooperation should be based on inducing a sense of confidence about a good outcome of the therapy and patient's reinte-

gration into family and social life. Respect for the person, as behavior and attitude, represents the fundamental value of the doctor-patient relationship and the essential condition of therapeutic success.

Family medicine brings a global and concise view of the man, represented in a close relationship with his social, existential, and family environment (1).

As the family doctor is the first step into the medical system, he has to be easy to find and approach by patients. The family doctor does not address a specific organ of the body or age group, but the entire person, the interconnections between different systems or organs and the external environment, the general manifestations of diseases, the associated and interdisciplinary pathology (2,3).

Also, family medicine has a nonspecific object of activity shared with other specialties, namely the early diagnosis of diseases, secondary prevention, community- based care in chronic diseases (tertiary prevention), continuous medical care, palliative medical care (4,5).

The family doctor is the only doctor that combines therapy and prevention activities (primary, secondary and tertiary prevention), both on an individual basis and at community level. Through the measures of prevention and health preservation, he is the guarantor of health (5,6).

Primary prevention measures may be effective if they target the individual, the family and the environment through concurrent actions of the family doctor and hygienist (e.g. vaccinations, health education, fighting the internal risk factors by acting on the environment through direct observation). Secondary prevention involves the perception of changes in the individual's health status and early diagnosis during common medical investigations and periodical examination. Tertiary prevention represents the prevention of complications and disease progression (5,6).

The main object of study for the family doctor is the individual, his family, his surrounding community and environment, all these exerting a positive or negative influence on the individual, with which the family doctor must be acquainted.

Family medicine distinguishes itself through the medical care given to healthy persons, primary prevention, and the holistic approach of the patient within the context of his environment, family, and living and working community, respectively (7).

This means that unlike other specialties that have in many cases analytic research methods of certain pathological conditions, that are exhaustively investigated, family medicine is solely based on methods that require synthesis, as the diagnosis is based on the synthesis of data collected through observation, history taking and physical examination of the patient.

Therefore, the research methods of family medicine are influenced by the following aspects: the family medicine is mostly communicative, mostly clinical, and mostly based on synthesis.

The activity of the family doctor mostly pursues clinical and diagnostic objectives, such as providing a diagnostic and therapeutic synthesis, therapeutical and prophylactic measures, as well as maintaining the health status of the healthy individual (7,8). The improvement of clinical methods resulted in the progress of family medicine.

The diagnostic and therapeutic synthesis is essential due to the fact thatthe encountered medical conditions are complex and that the patient should always be monitored (9).

In order to make and confirm a diagnosis, laboratory tests are required. This method of making the diagnosis is specific to all the other specialties, but cannot be ignored by the family doctor (9).

The family doctor should have basic knowledge of laboratory tests, based on which an initial diagnosis is possible. Based on this initial diagnosis the patient is either referred to a specialist or is recommended a first intention treatment. These methods of laboratory examination help the family doctor analyze and understand the diagnostic methods of other specialties, both at admission and upon discharge, in order to move the patient to community based care.

Due to the fact that global clinical laboratory testing uses the results provided by various specialties, where the patient was investigated, we come to the inevitable domain of interdisciplinarity.

DOCTOR-PATIENT DIALOGUE

The doctor-patient dialogue should take place in a relaxed atmosphere. The warm friendly tone, the optimistic attitude of the doctor, the solicitude, the comprehension towards patient's suffering, the kindness, the politeness and the patience with the person in illness, the interest that was proved by the doctor represent not only a real moral support, a source of security, of protection against the aggression affecting the patient. On the other hand, the patient becomes responsive, cooperative, understanding towards the efforts made by the family doctor in order to alleviate his suffering (1,7).

The patient becomes for the doctor a subject of research and of medical practice, but also a rational and social being, with a spiritual life and interest in his own health. Therefore, the doctor must be acquainted with the psychological peculiarities of the patient, irrespective of his disease.

As a good psychologist, the doctor shall make a close interhuman relationship with the patient, for the benefit of the latter. The doctor's emotional openness to the patient represents “the keystone of medical psychology”, as it lessens anxiety and insecurities and it humanizes the medical assistance.

The medical consultation begins with the report of the patient on the signs that were noticed at the onset of his disease. The report of the patient, based on recollection of pathological phenomena is known in the medical terminology as anamnesis or history. In quest of a thorough comprehension of data, the doctor asks questions, in order to set out some aspects. In other words, the doctor performs the medical enquiry (9,10).

The doctor-patient dialogue becomes more and more important, as the doctor helps not only treat the disease, but also solves the problems caused by diseases. In many chronic diseases, the communication is theoretically the only form of treatment. The advice, the support, the information are essential in helping patients adjust to a more limited lifestyle imposed by the disease.

ANAMNESIS COMPLEMENTED WITH INQUIRY

Anamnesis, complemented with inquiry, allows the doctor to gain extensive knowledge of patient’s symptoms. Thus, he has the opportunity to make an evaluation of his/her personality, level of intelligence, and general education, all these providing implicitly more nuanced criteria for evaluating the disturbances of the patient.

The adequate realistic description of symptoms, their succession have a great significance for the medical judgment based on a preliminary diagnostic hypothesis, whose accuracy shall be verified by clinical and laboratory investigations, but also by the results of the applied treatment (10).

The doctor-patient dialogue should be permanent, throughout the whole period of patient care. If the expected results do not occur, the doctor should do history again in order to gain new information that may lead to a reconsideration of the diagnosis (9).

The family doctor often makes the interdisciplinary synthesis in a flexible manner, either alone or in most cases with interdisciplinary consultation. In the latter case, the family doctor initiates the team work and makes the final evaluation by using the longitudinal follow-up. The onset of the disease may be suggestive for the nature and location of the pathological process.

The diseases with sudden onset and loud symptoms stand for acute pathological processes that allow an accurate diagnosis, based on the characteristic signs. An accurate diagnosis can even be made based on history alone. However, diseases such as cancer show progressive and silent clinical manifestations. The various locations of the neoplastic disease may have in early stages uncharacteristic, irrelevant clinical signs, common to other diseases of the affected individual (12). But it is a known fact that in cancer the symptoms are persistent, do not respond to common treatments, and the clinical picture adds further clinical manifestations (13).

In many cases, the description by the patient of the initial clinical symptoms is relevant for certain organs, such as lungs, heart, kidneys, and the presumptive diagnosis is verified through physical examination and laboratory tests. The subjective signs are common to various diseases of the respiratory system but take various forms and aspects, both at disease onset and during its progression, and the inquiry should focus on this problem (9). The infectious and contagious diseases are also important, because they weaken the body resistance and favor diseases of the respiratory system. In heart conditions, the patients complain of suggestive symptoms: pain in the region of the heart (precordial pains) with various characteristics, such as the typical constrictive claw-like pain that irradiates to the left shoulder, left arm and hand, and is common in angina pectoris or in myocardial infarction (7). Another common symptom is the lack of air or the difficulty of breathing that may frequently occur during exercise or even at rest.

The patients with high blood pressure may report such symptoms as seeing dark spots in the eyes or hearing various noises, headaches, and dizziness or sleep disorders. In diseases of the digestive system, the patients describe pains of different location and duration, depending on the affected area (stomach, duodenum, bowel, gallbladder), burning sensation behind the sternum or in the upper abdominal region, bloating. In diseases of the urinary system, the described symptoms include pain and alterations in urine elimination. Some patients report spontaneous urine leakage, that may suggest urinary incontinence, and in other cases urine retention. The qualitative changes in urine are medically significant and always alarming for the patients, when pus or blood is found in urine.

Very important is also that the doctor to

know the collateral genetic antecedents, because many diseases have a genetic basis (9).

During history taking, the patient should give information about age, sex, living and working conditions, conflicting events in the family or at work, if any, climate and geographical features of his neighborhood, unhealthy practices (use and abuse of alcohol and tobacco), treatments administered since disease onset, previous physical examinations and laboratory tests. The patients that received surgery should show the surgical protocol, needed in evaluating the acute disease each of these pieces of information may contribute to a more realistic approach of the investigated disease (14).

An as thorough as possible anamnesis and a correct inquiry represent "the art of interrogating the patients" and "the art of listening the patients". Anamneses that are incomplete and incorrectly recorded may be a source of errors, such as the unnecessary prescription of laboratory procedures, as well as of ineffective treatments. Thus, in some cases of pneumonia, the patients may report abdominal pain, that, as a result of a superficial and inaccurate anamnesis, may lead to a false diagnosis of appendicitis, cholecystitis or ulcer. Atypical clinical forms of severe disorders such as myocardial infarction may result in misdiagnosis and serious therapeutic errors (9). Some forms of myocardial infarctions are associated with digestive disturbances that include epigastric pain, meteorism, regurgitations, eructation that may induce a diagnosis of gastric or duodenal ulcer. In case of myocardial infarction, the treatment requires absolute bed rest, and if the diagnosis is false, this requirement will not be certainly satisfied and the outcome may be fatal (15, 16).

Anamnesis provides 50% of the information needed for a diagnosis. The rest comes from the clinical and laboratory examinations (17). It is common that the family doctor himself treat various diseases, such as, digestive, cardiac, dermatological, ophthalmic disorders, when the patient cannot receive the consultation of a specialist doctor or laboratory examinations, due to objective reasons.

Some medical or surgical specialties may change or event disappear, but in our opinion this is absolutely certain: in all ages, as Hippocrates specified almost two thousand five hundred years ago, the family doctor will be always present with his patients by word and deed and with heart and soul (10).

CONCLUSIONS

The profession of family doctor is a noble one. The family doctor has difficult tasks to undertake, many financial disadvantages, but, on the other hand, he has great satisfactions.

The continuing medical education is essential for the life of a family doctor. The profession of doctor is one of the occupations that necessarily require lifelong education. Moreover, the health education of the population should represent the main aim of the national health policy, along with objectives such as medical preventive measures. The improvement of the level of health education in the general population may be achieved through large educative programs of public health.

Based on the duties of a family doctor, we can conclude that the family medicine represents the most important branch of medicine, because it provides the primary care and differentiates between the truly severe cases, that require hospital admission and the cases that require outpatient

care, under modern and efficient conditions.

What the family doctor does is essential, because he has a holistic view of the patient.

The family doctor should be regarded as "the hub of the world", because he deserves that. But until his status will be acknowledged, the family doctor may be still compared with an armed infantryman, who enters minefields, investigates the enemy, fights successfully or unsuccessfully, while on duty, and watches the sky full of specialists who look at him from aircrafts. However, when brought down to earth and put in the front line, these specialists behave just like untrained infantrymen.

CHRONIC VENOUS INSUFFICIENCY STAGE V CEAP SECONDARY TO HEREDITARY THROMBOPHILIA AT A YOUNG MAN

F. Mitu[1,2], Adina M. Țurcanu[3]

3. Clinic of Pulmonary Diseases

CHRONIC VENOUS INSUFFICIENCY STAGE V CEAP SECONDARY TO HEREDITARY THROMBOPHILIA AT A YOUNG MAN (Abstract): Hereditary thrombophilia is a rare disease of general population, which is responsible for debilitating consequences in severe cases. We present the case of a young male patient whose pathology and symptoms occurred since the age of two, which determined a venous insufficiency stage V with important limitation of the locomotors ability and plenty of complications. The aim of this paper is to draw attention to a disease that sometimes is not diagnosed on a first visit to the doctor.
Keywords: HEREDITARY THROMBOPHILIA, ANTITHROMBIN, FACTOR LEIDEN.

Hereditary thrombophilia is a rare condition that manifests as several abnormalities determined by hereditary thrombophilic factors that can act by reducing the number of inhibitors which can lead to clotting or can increase the number or the function of clotting factors (1, 3, 4, 5, 6).

The factors involved in thrombophilia pathology are: resistance to activated protein C, factor V Leiden, protein C or S deficiency, mutation of the prothrombin gene, anti-thrombin gene, and increase of F VIII a, hyper-homo-cysteinemia.

The antithrombin deficiency of the overall population is around 0.015%-1.00% (1, 2). It is present in 0.5%-7.6% of patients diagnosed with venous thromboembolism. There are three known subtypes of antithrombin deficiency produced by more than 200 different mutations. Most of the mutations are heterozygous; the homozygous type is not life-compatible or determines a severe thrombotic phonotype. From a physiological point of view, antithrombin III has a covalent bond and makes trombone and factors Xa, IXa, XIa and XIIa inactive (1, 3, 5, 6, 7, 9, 10, 11).

Resistance to reactive protein C is given by a mutation at the level of the position 1691 of the factor V Leiden and represents the most frequent thrombophilia cause, being present in more than 40% of the diagnosed cases. Most homozygotes develop at least one thrombotic event throughout life, but have a lower risk than the other factors involved in the pathology of hereditary thrombophilia. In addition, factor V Leiden is met in overall population in a

percentage of up to 15%; on patients with recurrent thromboses it is met in up to 50% (1, 2, 4, 6, 7, 9).

The association of more hereditary thrombotic factors tends to lead to an increase of complications and to the influence of the diagnostic.

Virchow's triad is represented by: injury to the vessel walls, abnormal blood flow and changes in blood structure. Some authors state that about 60% of the patients with hereditary deficiency of antithrombin III develop a thrombotic episode until the age of 60 (1, 2, 3).

CASE PRESENTATION

We are going to present the case of a male patient, aged 28 years, who was admitted at the Cardio-Vascular Clinic of Iasi and accused important pains at the level of the lower right limb, leg ulceration, oedema of inferior legs, asthenia, vertigo, scotomas.

From the hereditary-collateral history it can be identified a familial aggregation of varicose cases located at legs' level (two sisters, one brother, two cousins on the mother line, grandfather on the mother line, mother) and oesophageal varicose (one brother).

The previous pathological history of the young man, ex-smoker of 5 packs a year highlight the fact that he was diagnosed with abdominal varicose and chronic venous deficiency at the age of 2, with varicose at the level of inferior limbs, varicose ulceration at the level of the right calf and deep thrombophlebitis at the age of 6 and in 2007 he received the diagnostic of congenital malformation of the venous system (fig. 1).

The clinical examination on the apparatus and systems reveal the presence of varicose veins at abdominal level and on the inferior legs, as well as the presence of bilateral calf ulceration of 10/5 cm, additional trophic disorders, ochre dermatitis (fig. 2 a, b, c). The examination of the cardio-vascular system reveals a systolic murmur II/III in the mitral valve.

Fig. 1. Varicose veins at abdominal level and on the inferior legs of the patient at puberty

Paraclinical investigations highlight the seriousness of the chronic venous deficiency. Venous Eco Doppler examination does not highlight a venous flow at the level of the superficial femoral veins and popliteal veins. Venous tracts are slightly visible, having a reduced diameter, echogenous on the inside and lacking in flow. Varicose tracts are visible at the calf and thigh level.

Abdominal ultrasounds reveal a spleen with homogenous structures, 152 mm, and small vascular hilum dilatations.

The performed ultrasound revealed a mitral deficiency of degree I-II Doppler,

tricuspid deficiency degree I Doppler, PSAP – 36 mmHg, small calcified structures, especially at the level of the posterior aortic wall.

Fig. 2 a, b, c. Varicose veins at abdominal level and on the inferior legs at the age of 28 years.

Following clinical and paraclinical examination, there is a suspicion of hereditary thrombophilia and a genetic examination is requested. It is recommended to perform diagnostic molecular tests. Following analyses, it was observed an antithrombin III deficiency (51.3% compared to standard values, which are between 75-125%), and a factor V Leiden of 49 (the standard value is 60-140%).

Considering anamnestic, clinical and paraclinical data, it is given the diagnosis of hereditary thrombophilia by antithrombin III deficiency and abnormal factor V Leiden. In addition, there are also given the diagnoses of chronic venous deficiency at legs level, class V CEAP, healed varicose ulcer on the bilateral calves, ochre dermatitis on bilateral calves, slight mitral deficiency, slight tricuspid deficiency, aortic atheromatosis.

DISCUSSION

Hereditary thrombophilia is a rare disorder which affects patient's life quality and implies a guarded prognosis for serious cases. What is so particular about this case are the severe changes observed during clinical and paraclinical examination. The management of this disorder requires the cooperation the patient, family, as well as a medical team made of surgeon, radiologist, internist, geneticist and physical therapist.

EFFECT OF FIBER POST LENGTH AND ADHESIVE STRATEGY ON FRACTURE RESISTANCE OF ENDODONTICALLY TREATED TEETH

When restoring an endodontically treated tooth with excessive loss of tooth structure, a post may be needed to improve the retention of the core build-up material. Post material, design, dimensions, surface roughness and length have been shown to affect fracture resistance and retention. Nowadays, thanks to the optimization of bonding mechanisms of current adhesive composite cements, guidelines regarding post length may be revised. Since fiber posts are bonded within the root canal, their length could perhaps be shortened in light of a less invasive post build-up. The aim of this study was to evaluate the effect of the length of fiber-posts and type of adhesive cement on the fracture resistance of endodontically treated teeth, after fatigue loading. Eighty extracted upper pre-molars were sectioned at the cemento-enamel junction and endodontically treated. After 24 h of water storage at 37 ^{o}C, RelyX Posts (3M-ESPE) were cemented with Panavia F 2.0 (Kuraray) or RelyX Unicem (3M-ESPE). A standardized composite core was built. Specimens were divided into four groups depending on the post–core ratio and submitted to 1,200,000 cycles using a chewing simulator (Willytech). Immediately afterwards, all specimens that survived fatigue loading were fractured using a universal loading device (Micro-tester, Instron). Data were analyzed with ANOVA. Four percent of the specimens failed during fatigue loading. The length of the post into the root affected the fracture resistance, the control group (with the greatest length of the posts) always having the lowest fracture resistance. The type of adhesive cement did not affect the fracture resistance. A prevalence of not-repairable failures was observed in specimens restored with the longest posts, whilst shorter posts led to more repairable failures. The results suggest that shortening the post length and the preservation of more tooth structure, offer the potential for reparability through an in-built fail safe mechanism and may thus reduce the occurrence of catastrophic failures (Zicari F, Van Meerbeek B, Scotti R, Naert I. Effect of fiber post length and adhesive strategy on fracture resistance of endodontically treated teeth after fatigue loading. *Journal of Dentistry* 2012; 40: 312-321).

THE SEMI-QUANTIATIVE CALPROTECTIN RAPID TEST – IS IT USEFUL IN INFLAMMATORY BOWEL DISEASE? (Abstract): **Aim**: To assess the efficiency of the dosage of the semi-quantitative calprotectin rapid test in evaluating the activity of inflammatory bowel diseases. **Material and methods**: The prospective study included 87 patients with BII (50 with ulcerative colitis, 37 with Crohn disease) hospitalized between January 2011 - May 2012. The diagnosis was confirmed by colonoscopy and histological examination. Fecal calprotectin was measured by means of a semi-quantitative rapid test. **Results**: There were 50 patients with UC and 37 with BC. 96% of the UC patients were evaluated during the active disease. 21 of them had a severe episode of active disease, 16 had a moderate one, while 10 had a mild activity episode. The correlation between the calprotectin values and lesions localization was analyzed, without finding any statistical differences. The data have shown a very strong correlation between the severity of the active disease, assessed through the UCDAI (Mayo) score, and the calprotectin value. Patients with CD manifested a linear correlation between the severity of the active disease and the calprotectin value. **Conclusions**: The rapid test for assessing calprotectin could be a useful non-invasive marker in appreciating the severity of clinical and biological disease activity. **Key words**: CALPROTECTIN, INFLAMMATORY BOWEL DISEASE, ULCERATIVE COLITIS, CROHN'S DISEASE.

Inflammatory bowel disease (IBD) is a group of chronic idiopathic affections represented by ulcerative colitis (UC), Crohn's disease (CD), and undetermined colitis. During the last decades, there has been noted a growth in the occurrence and prevalence of these affections (1). The clinical activity score (CAS) indirectly assesses the activity of the disease and predicts, with low accuracy, the endoscopic inflammatory activity. Endoscopy and histological examinations are precise, but they are expensive and invasive methods. Given the context, there have been some recent rising concerns over the highlighting of the biomarkers that can be used to quantify the activity of the disease and the risk of relapse (2, 3).

Calprotectin is a protein that plays a central part in the immune defense mechanism. Fecal calprotectin can be used as an indirect marker of intestinal inflammation.

It is very stable in feces and its concentration is very well correlated to the activity level of BII (4, 5).

The aim of the study was to assess the efficiency of the dosage of the semi-quantitative calprotectin rapid test in evaluating the activity of inflammatory bowel diseases.

MATERIAL AND METHODS

A descriptive prospective study had been conducted, between January 2011 and May 2012, on 87 BII patients admitted to the Gastroenterology and Hepatology Center of "St. Spiridon" Hospital in Iaşi. The diagnosis was formulated based on clinical, biological, and endoscopic manifestations, and it was confirmed by a histopathological examination. An endoscopic examination established the extension of the lesions. The UCDAI score was used in order to assess the severity of the disease for the UC patients, while the CDAI score was used for the CD patients.

Fecal calprotectin was determined by rapid immunochromatographic semi-quantitative test CalDetect® Sofar. The presence of a first band (T1) indicates a calprotectin concentration lower than 15 µg/g, which is not representative for bowel inflammation. The presence of a second band (T2) demonstrates a fecal calprotectin concentration between 15 µg/g and 60 µg/g. This shows an acute inflammation of the bowel mucosa. The third band (T3) is present at calprotectin concentrations higher than 60 µg/g and it signals a high degree of inflammation of the bowel mucosa.

The Chi-squared test, t-student, and Spearman and Pearson regression tests were used for statistical analysis.

RESULTS

The study included 50 cases of UC and 37 cases of CD. 96% of the UC patients were evaluated during the active disease. 21 of them had a severe episode of active disease, 16 had a moderate one, while 10 had a mild activity episode.

Analysis of individual parameters (age, sex, and location) did not show significant correlations.

The correlation between the calprotectin values and lesions localization was analyzed, without finding any statistical differences (fig. 1).

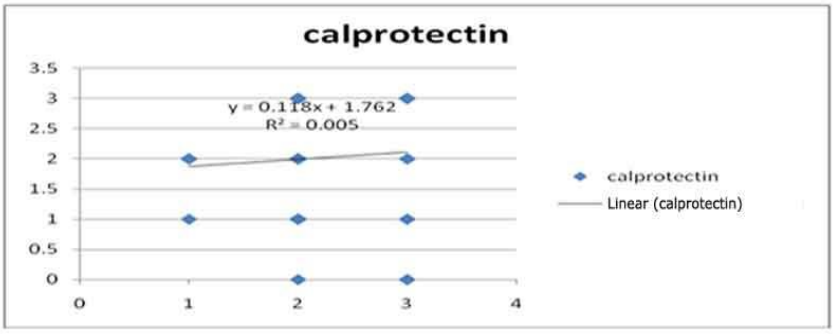

Fig. 1. Correlations between the calprotectin value and the extension of lesions for UC patients

The data have shown a very strong correlation between the severity of the active disease, assessed through the UCDAI (Mayo) score and the calprotectin value (fig. 2), a result confirmed by the Spearman regression (fig. 3).

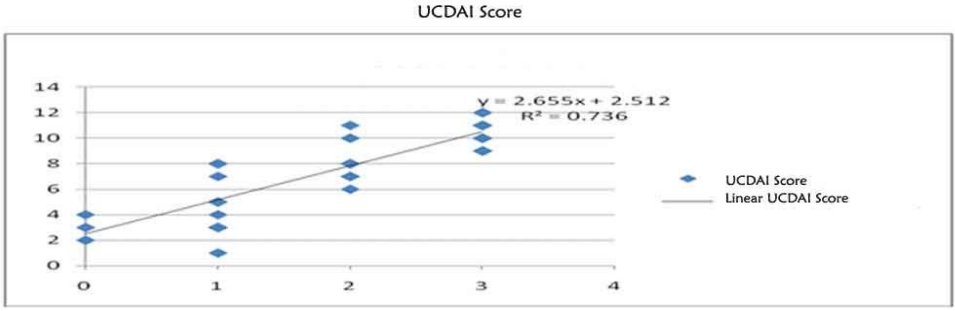

Fig. 2. Correlations between the calprotectin value and the active disease for UC patients

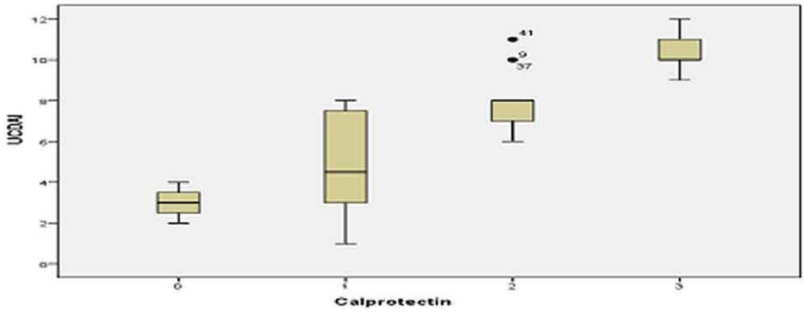

Fig. 3. Correlations between the calprotectin value and the active disease for UC patients

Thirty six patients with UC were studied. Four of them were in remission. As regards the active disease, 11 patients had a moderate active disease, while 11 presented mild active disease. Only 3 patients presented a severe active disease.

Crohn's disease is classified according to the Montreal classification scheme, which uses age, lesions localization, and behavior as individual parameters. The study found no statistically significant correlations between calprotectine and any of these parameters, localization in particular (fig. 4)

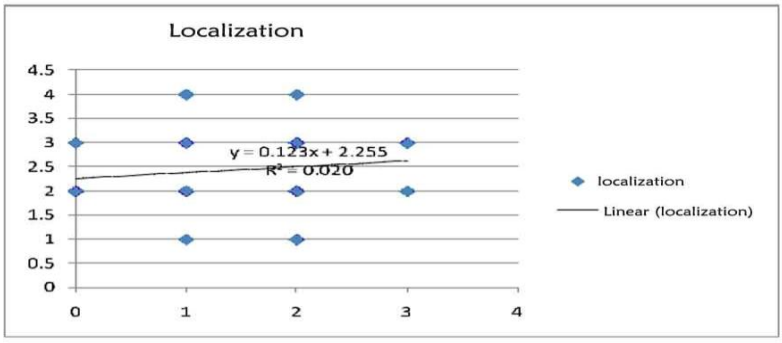

Fig. 4. Correlations between the calprotectin value and the lesions localization in CD

In CD, we noticed a linear correlation between the severity of the active disease, assessed through the CDAI score, and the calprotectin value (fig. 5, 6).

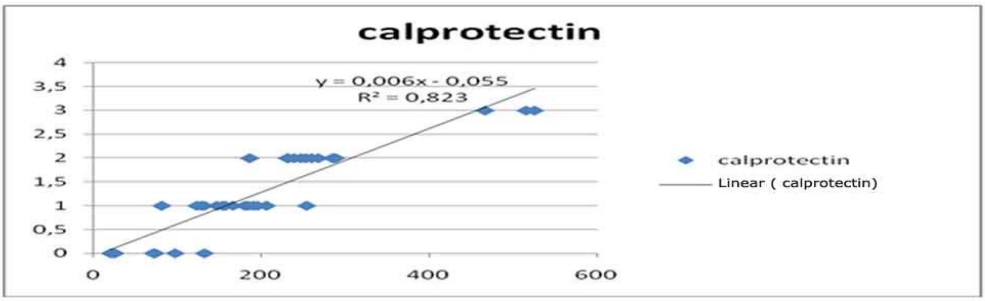

Fig. 5. Correlations between the calprotectin value and the disease activity in CD

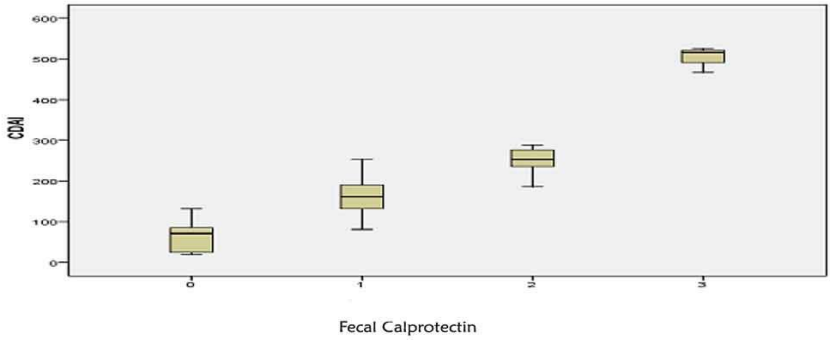

Fig. 6. Correlation between the calprotectin value and the disease activity in CD

DISCUSSION

There is a real concern regarding the discovery of a non-invasive marker with a high power of prediction for inflammatory bowel diseases and severity of active disease. The most promising markers have proven to be the fecal markers: calprotectin and lactoferrin. These proteins were found in large concentrations in intestine inflammation. Numerous recent studies have shown a good correlation between the endoscopic and histological activity of the disease and the fecal calprotectin value (4, 5, 7-10).

Recent studies have highlighted the utility of calprotectin in monitoring the patients in order to predict the relapses (6).

However, few studies use rapid tests in order to assess active disease (9, 10).

This study is prospectively evaluating the importance of the semi-quantitative calprotectin rapid test in assessing the activity.

The univariate analysis of data did not show any correlation between individual parameters (age, sex, location). The data available in literature indicate some correlations between the individual particularities and disease activity, without being statistically significant (3). Surprisingly, the calprotectin value did not correlate significantly with the extension of lesions in UC or the localization in CD. The data available is controversial. Some studies highlight correlations (8), while others

failed in establishing associations with the calprotectin values (6).

The data show a very good correlation between the severity of the active disease and the calprotectin value, not only for UC, but also for Crohn's disease. This suggests that the immunochromatographic semi-quantitative test CalDetect® Sofar is reliable in the evaluation of the disease activity and might be an alternative to the existing tests. The data are similar with those available in literature (9,10).

At the moment, the study does not analyze the correlation with other consecrated inflammation markers (leukocytosis, thrombocytosis, ESR, PCR), nor the endoscopic score, both being cited as having a very good correlation with the calprotectin value.

CONCLUSIONS

The rapid test for assessing calprotectin could be a useful non-invasive marker in appreciating the severity of the clinical and biological disease activity.
